The disease arises more commonly in the prostate and vesicles than in the epididymis.

Genital tuberculosis is ultimately accompanied by tuberculosis of the lungs or kidneys in a large percentage of cases.

If the seminal vesicles are involved, adequate drainage is not furnished by the ejaculatory ducts, and from

Fig 5—The tuberculous epididymis is being cut off from the testicle by the cautery after which the testicle is returned to the scrotum.

this region the disease progresses downward to the epididymis or upward to the kidneys or lungs.

The presence of renal tuberculosis, which has occurred in about 30 per cent of the cases, is no bar to carrying out the radical operation, in addition to nephrectomy, and curative results may thus be obtained.

The presence of old or recent tuberculosis of the lungs is often no contraindication to the radical operation, in fact, it is one's duty to assist, if possible, in the arrest of pulmonary tuberculosis by removing the external foci of tuberculosis.

If the disease is apparently localized within the scrotum, most careful examinations should be made to rule out involvement of the vesicles and prostate before relying entirely on epididymectomy, which generally will not arrest tuberculosis of the vesicles.

Fig 6—Method of traction (alternating between operator in groin and assistant pulling on clamp in perineal wound on vas) by which vas is freed and then drawn out through inguinal canal.

The radical removal of the seminal tract, both epididymides, vasa, vesicles and lateral lobes of the prostate is the operation of choice in the treatment of genital tuberculosis.

ABSTRACT OF DISCUSSION

DR W F BRAASCH, Rochester, Minn. All are aware that in Dr Young's hands the operation that he so well described is unquestionably a procedure that is worthy of serious consideration. However, that the average urologic or general surgeon can do as well is decidedly open to question. This is evidenced by the fact that although not many such operations have been performed, I have observed three patients operated on elsewhere who came because of a permanent urethrorectal fistula. Furthermore, one must hesitate to advise an operation that even in the most skilful hands has an immediate and late mortality as high as is shown by Dr Young's figures. In the first place one must decide whether so radical an operation for pangenital tuberculosis is necessary. It is well known that in cases of renal tuberculosis evidence of some form of genital tuberculosis is present in the great majority of cases. Among some 1,200 patients operated on for renal tuberculosis at the Mayo Clinic, evidence of involvement of the genitalia was discovered on clinical examination in approximately 80 per cent. Most urologists have found surgical treatment advisable only in the epididymis or testicle. Why should the tuberculous epididymis or testicle be operated on? Largely because of the common tendency to suppuration and formation of abscess. In contrast suppuration of the prostate or the seminal vesicles is rarely observed. The late mortality following nephrectomy for renal tuberculosis in patients with evident involvement of the prostate and seminal vesicles is no higher than among those without such an involvement. This is shown by the fact that among the female patients operated on for renal tuberculosis, most of whom have no evidence of involvement of the genitalia, the late mortality was little if any less than in the males. What would be the best procedure in the presence of tuberculosis involving all of the genitalia? Tuberculosis of the epididymis is arrested by heliotherapy in many cases, as has been shown by a number of observers. The great difficulty, however, in advising patients to use heliotherapy is the difficulty of securing adequate radiation. Furthermore, extension of the disease in the epididymis with involvement of the testicle is

sometimes observed in spite of ideal irradiation I have observed that the tuberculous epididymis is best removed surgically before suppuration takes place and that heliotherapy should be employed as an adjunct. In this way suppuration and involvement of the testicle can be obviated. Reexamination of patients in whom tuberculosis of the prostate and seminal vesicles was found five or ten years afterward shows that nature has taken care of these tissues. On rectal examination but little evidence of the previous infection is usually made out. In some, cicatricial areas may be felt, in others, the prostate and vesicles seem to have atrophied. In only an occasional case is there any evidence of an active tuberculous process. The burden of proof still rests with Dr. Young in showing that the late mortality following complete removal of the genitalia is any better than when left alone.

DR C. J. McDEVITT, Cincinnati: Early diagnosis and radical removal of genital tuberculosis offers the greatest hope of cure. With active pulmonary tuberculosis complicating the picture, however, one is justified in withholding surgical therapy a reasonable length of time in the hope of first arresting the pulmonary lesion.

THE INCIDENCE OF RENAL TUBERCULOSIS

IN FIVE HUNDRED AUTOPSIES FOR PULMONARY AND EXTRAPULMONARY TUBERCULOSIS

MONROE E. GREENBERGER, M.D.

LEONARD PAUL WERSHUB, M.D.

NEW YORK

AND

OSCAR AUERBACH, M.D.

STATEN ISLAND, N. Y.

After a careful survey of the literature it is amazing to learn of the various opinions and theories concerning renal tuberculosis. It comprises 30 per cent of all surgical lesions of the kidney, being more than twice as common as renal tumors. The disease usually afflicts persons in the prime of life and, if not successfully treated, may lead to extensive involvement of the genito-urinary system.

Despite advances made in the recognition and treatment of renal tuberculosis, the disease is often overlooked. In a service confined to a large institution caring for tuberculosis in its various forms, one becomes "tuberculosis conscious" and ever on the alert for manifestations of this disease in the genito-urinary system. But in private practice and in a general hospital where tuberculosis is infrequently encountered involvement of the genito-urinary tract is often overlooked. This is especially true in early renal tuberculosis, in which symptomatology is markedly deficient and routine physical examination fails to reveal evidence of extrarenal tuberculosis.

We believe that neglect in recognizing tuberculosis in other parts of the body often leads to a failure in the recognition of early kidney involvement. To make a diagnosis of renal tuberculosis after extensive caseation and excavation has occurred is no difficult task. The recognition of early preclinical renal tuberculosis requires the greatest care, and until some reliable method is developed every effort must be made to correlate all clinical, roentgenologic and pathologic data. For this reason we submit the present compilation of statistics.

From the Departments of Urology and Pathology, Sea View Hospital, City of New York Department of Hospitals.
Read before the Section on Urology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

SOURCE OF MATERIAL

The material that forms the basis of this report was gathered from Sea View Hospital, a 1,750 bed institution. This is a municipal tuberculosis hospital situated on Staten Island in New York harbor. The report

Fig. 1—Kidney that was of normal size (the illustration is about seven tenths the size of the original). Capsule stripped easily leaving a smooth surface studded with a number of varying sized yellowish white areas extending into the kidney substance. Similar areas are present on cut surface both in the medulla and in the cortex. The pelvis, calices and ureter are normal.

covers the period from June 1932 to April 1934. The data were obtained from routine postmortem examinations correlated with the clinical observations obtained by the careful analysis of the history of each case.

Fig. 2—The surface of both kidneys shows irregularly distributed numerous small yellowish white areas which on section seem to extend into the kidney substance. Both ureters are dilated but at the ureteral pelvic junction of the left kidney there is a sharp double kink which effectively obstructs the lumen. The upper left calix is so enlarged that it reaches into the cortex.

Of the 500 cases in which necropsy was performed, 252 showed evidence of tuberculous infection as shown in the accompanying table. Miliary tubercles were found in 228, or 45.6 per cent. By this we mean small tubercles that can be recognized grossly (figs. 1, 2 and 3). They are gray or yellow, are single or conglomerate.

erate, and often lie in rows and follow the medullary rays into pyramids. Microscopic examination of these sections revealed that they vary from necrotic areas to fibrotic tubercles. These necrotic areas showed a number of polymorphonuclear leukocytes and acid-fast bacilli when stained with Ziehl-Neelsen's stain. Hyperemia was present in the remaining portion of the kidney but was more pronounced in the tissue adjacent to the tubercle.

In this group the disease was found to be bilateral in 187 cases, or 82 per cent, and unilateral in forty-one cases, or 18 per cent. The youngest patient of this group was 9 months old and the oldest 74 years. The average age was 36. There were 157 males, seventy-one females, 154 of the white, seventy-two Negroes and two of the yellow race in this group. Only 25 per cent had urinary symptoms. The most common complaint was nocturia and frequency.

Fig 3—This kidney was slightly larger than normal. The capsule stripped with ease, leaving a smooth surface on which there are a number of small yellowish white areas extending into the cortex. The calices pelvis and ureter show no evidence grossly of pathologic change.

Of the 500 cases in which necropsy was done, organ tuberculosis was found in only twenty-four cases, or 4.8 per cent. By organ tuberculosis we mean a destruction of the kidney substance. In the early cases there was often an area of caseation in the cortex of the upper pole (figs 4, 5 and 6). This area of caseation extended through the medulla to the calyx adjoining it. When the area of caseation liquefies, a cavity results. In a fully developed "organ tuberculosis" there is extensive destruction of the kidney parenchyma (figs 7, 8, 9 and 10).

In this group the disease was found to be bilateral in thirteen cases, or 54 per cent, and unilateral in eleven cases, or 46 per cent. The youngest of the group was 23 and the oldest 59 years of age. The average age was 39. There were twenty men, four women, twenty-one of the white race and three of the Negro race in this group. Sixty per cent of the cases in this group presented some evidence of urinary disturbances surprisingly mild as compared to the pathologic changes found at the postmortem table.

In sixteen cases the tuberculosis was extrapulmonary and the renal involvement bilateral. In all but one it

was of the miliary type. The youngest of this group was 1½ years and the oldest 56 years of age. The average age was 22. There were nine males, seven females, five of the white, ten of the Negro, and one

Fig 4—Bilateral pyelogram revealing tuberculosis of the upper pole of the left kidney.

of the yellow race in this group. The outstanding cause of death was tuberculous meningitis, ten; tuberculous peritonitis, four; generalized miliary tuberculosis, two.

Fig 5—Same case as in figure 4. Kidney injected with sodium iodide after removal. Lesion in the upper pole of the kidney.

COMMENT

Certain allowances should be made for differences of opinion regarding histologic interpretations. Young adults in whom gross examination revealed scar forma-

tion microscopically showed circumscribed areas of fibrous tissue. The kidney showed no evidence of arteriosclerosis. Such a lesion could be classified only as healed tuberculosis by inference.

In the terminal stage of pulmonary tuberculosis, hematogenous dissemination of tubercle bacilli is a

surprisingly lacking, as shown in our series. This has been confirmed by other observers and is explained by the absence of tuberculous involvement of the ureter and bladder.

The observations of other investigators are of interest, for they report that more than 30 per cent of the victims of genito-urinary tuberculosis succumb to miliary tuberculosis and tuberculous meningitis. Such a preponderance of tuberculous meningitis as the cause of death was not encountered in our cases.

It is our belief that careful postmortem examination will often reveal a high incidence of bilateral miliary renal tuberculosis. This must not be interpreted as meaning that clinically bilateral miliary renal tuberculosis is common but rather that this occurred as a terminal manifestation of the disease a few weeks prior to death.

Mention has repeatedly been made of the greater preponderance of tuberculosis among the Negro race as compared to the white race. In our series, 69 per cent of the cases presenting renal tuberculosis were of the white race. This percentage corresponds to the proportion of white inmates at Sea View Hospital and must not be taken as an index of the virulence of the disease in the white race. An average census taken during the period of this study from June 1932 to April 1934 shows between 1,750 and 1,800 beds occupied. During this period there were admitted 3,224 white patients, as compared with 807 Negro and twenty-seven yellow patients.

SUMMARY

- 1. An attempt has been made to correlate the incidence of renal tuberculosis in 500 cases of pulmonary and extrapulmonary tuberculosis.
- 2. Statistics reveal the high incidence of bilateral renal tuberculosis.
- 3. The nondestructive, closed or miliary lesion is common.

Fig. 7.—Kidney that was slightly larger than normal. Tuberculous excavation with almost entire kidney involved.

Fig. 6.—Same case as in figures 4 and 5 demonstrating relatively early involvement of tuberculosis of the kidney. Excavation is present.

frequent occurrence and macroscopic and microscopic tubercles can be found in the liver, spleen and kidneys. These areas of tubercle formation found at the necropsy table are not to be regarded as evidence of previously existing clinical tuberculosis but as a phase of the terminal stage of the disease.

It is probable that this explains the unusually high percentage of miliary tuberculosis found in our series.

Number of Cases (252, or 50.4 per Cent) Presenting Renal Pathologic Changes

	Male	Female	White	Negro	Yellow	Miliary Tubercles		Organ	
						Bilateral	Unilateral	Bilateral	Unilateral
Chronic pulmonary tuberculosis	454	168	68	170	65	172	41	12	11
Extrapulmonary tuberculosis	16	9	7	5	10	15	0	1	0
Total	500	177	75	175	75	223	41	24	11
		25.2	25.2	25.2	25.2	45.6%		4.5%	

Clinically this type of renal infection is of little significance. It rarely is accompanied by urinary symptoms, has no radiographic signs of alteration in the renal architecture, and is demonstrable only at postmortem examination. This type is commonly referred to as the nondestructive, closed lesion.

Organ tuberculosis is the pathologic condition most frequently encountered by the clinician and urologist. It is the type of lesion that shows definite pyelographic changes and is clinically recognizable. Despite marked renal involvement, symptoms in this group are often

4. The destructive, open, organ or chronic surgical tuberculosis of the kidney is notably deficient in symptoms despite the advanced renal involvement.

5. Pulmonary tuberculosis appeared as the primary focus of infection.

40 East Sixty-First Street.

ABSTRACT OF DISCUSSION

DR. ROY B. HENLINE, New York This study shows additional evidence of the frequency of kidney infections secondary to tuberculosis elsewhere in the body. Probably most other renal infections reach the kidney similarly by way of the blood stream and form small infected areas, which follow the medul-

Fig. 8—Hypertrophied kidney. Extensive excavation of upper and lower calices. Multiple areas of caseation with central excavation.

lary rays into the pyramids. This may therefore be a basis for more clearly understanding the earlier phases of all kidney infections and permit more intelligent treatment. The miliary tubercles found in 45 per cent of these 500 necropsies are probably the pathologic entities that have given rise to the term 'preclinical' or silent stage of tuberculosis. This stage of renal tuberculosis is never recognized clinically. However, the same phase of a pyogenic infection so-called pyelitis is commonly seen in children who manifest normal urine, fever and prostration for from twenty-four to forty-eight hours followed by a shower of pus and bacteria in their urine as the infection gains an exit into the kidney pelvis. Further evidence that small tubercles in the renal cortex may heal corresponds to the recent generally accepted views. These healed lesions are rarely seen except at autopsy, and conclusive proof that they are tuberculous in origin is lacking. Bilateral renal tuberculosis was present in almost 80 per cent of the 252 cases in which tuberculous infection of the kidneys was found. This percentage of bilateral involvement is much larger than one finds clinically and thus many of these infections must have occurred shortly before death. Less than 5 per cent showed gross renal destruction and less than half of these were unilateral. Of ninety-seven cases of nephrectomy for tuberculosis in my services in New York City, less than 5 per cent showed any gross evidence of bilateral involvement as determined by the renal function test, infected urine or pyelogram. Since we are concerned with the problem of treating tuberculous kidneys, one must believe that bilateral clinical renal tuberculosis is rare. The symptoms of renal tuberculosis in no way correspond to the kidney damage. Many grossly destroyed kidneys manifest very few urinary symptoms, while a very small lesion may give rise to severe bladder and general symptoms. This obviously depends on the lesions in the bladder. It is my opinion that some types of renal tuberculosis will heal spontaneously that tuberculous bacilluria without renal disease does not exist that a tuberculous kidney should be removed when pyelographic evidence shows the occurrence of destruction and when the function is diminished that bilateral renal tuberculosis occurs more often than was formerly believed and that in some patients

in whom bilateral renal tuberculosis has been diagnosed removal of the destroyed kidney offers the greatest hope of benefit to the patient.

DR. THOMAS D. MOORE, Memphis, Tenn. The frequent terminal involvement of the kidneys with miliary tubercles in patients dying of general or pulmonary tuberculosis is of more academic interest to the urologist than of practical importance. Renal tuberculosis of the type referred to by the authors as 'organ tuberculosis' is of paramount importance and occurred in about 5 per cent of their cases. This complication is evidently commonly overlooked or neglected in institutions caring for tuberculous patients. In a 300 bed sanatorium near Memphis a member of the staff stated that they were interested chiefly in the chest, that genito-urinary symptoms and pyuria were seldom investigated urologically and that patients with urinary involvement seldom did well. In a study of the records in six sanatoriums for the tuberculous Young noted evidences of the disease in the urinary tract in seventeen cases. Cystoscopy and ureteral catheterization had been employed in only three. It was noted that when the genital or urinary tracts became involved the outlook was unfavorable and that most of these patients died. Institutions with a record of a high percentage of cures of pulmonary tuberculosis may show in marked contrast, a 100 per cent mortality record in cases with renal disease. On the other hand it is not uncommon to observe the rapid improvement in the condition of a patient with pulmonary tuberculosis after the removal of a tuberculous kidney. The nephrectomy enables his defenses to become concentrated on the pulmonary process with beneficial effect. This is especially true if the operation has been performed under paravertebral nerve block or spinal anesthesia thus avoiding the insult to the lungs of a general anesthetic. Those specializing in tuberculosis should be impressed with the absolute need of alertness in recognizing involvement of the genital and urinary tracts. It

Fig. 9—Moderate enlargement of kidney. Multiple renal calculi. Multiple areas of excavation with productive tissue reaction at periphery.

behooves urologists to bring to their attention that radical surgical measures adopted early will combat in an effective way the bad results so common at present.

DR. WILLIAM ROSENBERG, Cleveland. Many of the changes in renal tuberculosis may be explained on the basis of bacterial allergy. Certain lesions of the kidney are probably dependent on the degree of sensitization of the cells and the size of the

shocking dose of the tubercle bacilli or their toxins. The greater the dose for a given sensitivity, the more extensive the exudative phenomena that result.

DR. FREDERICK LIEDERTHAL, Chicago. In all cases of tuberculous renal bacilluria, the kidneys should be examined very carefully. It is amazing how many pathologists expert in their field, will merely open the pelvis and split open the ureter without looking at the renal papillae. If one will take scissors, however, and split open every calyx to its very termination and examine every renal papilla carefully, one will be sure to find a tuberculous lesion on a renal papilla in every case in which tubercle bacilli have been demonstrated in the ureteral catheter specimen of urine. If this procedure should be followed in every doubtful case, fewer reports would be found in the literature of a so-called tuberculous renal bacilluria without a tuberculous renal lesion. On the finding of such a minute specific renal lesion rests the disproof of the existence of a tuberculous nephritis in each given case.

DR. MONROE E. GRENFBERGER, New York. At Seaview Hospital we are in a sort of urologists' utopia, because of the cooperation that exists between our department and the attending medical staff. The medical director Dr. George G. Ornstein is surgically minded and is in complete accord with the

Fig. 10.—Kidney that was smaller than normal. Extensive productive changes predominating. Tuberculous abscesses surrounded by thick fibrous tissue.

urologists' point of view in the treatment of renal tuberculosis. In the majority of sanatoriums throughout the country, as Dr. Moore pointed out, it is most difficult to obtain permission to operate or even to work up a case. The report that we presented covered only our autopsy studies. We have been fortunate in operating in a number of cases and obtaining results corresponding to those reported by others throughout the country. The patients live longer and in greater comfort than they would if treated only medically.

Probably Once in Fifty-Seven Million Confinements—As plural births go, twins are fairly common about one in 87 confinements giving rise to twins. But the scarcity of plural births goes up very fast with the number born at one confinement. It has in fact been pointed out by W. W. Greulich of the University of Colorado that the scarcity increases approximately like the powers of 87, while one confinement in 87 brings twins into the world triplet births would be expected about once in 7,569 confinements, this number being the square of 87, and quadruplets once in 658,503 births this being the cube of 87. If this law continued for higher orders of plural births we should expect quintuplets once in 57 million confinements.—*Statist. Bull. Metropolitan Life Insurance Company*, July 1934.

THE EFFECT OF ATHEROSCLEROTIC PLAQUES

ON THE DIAMETER OF THE LUMEN OF
CORONARY ARTERIES

JAMES D. STEWART, M.D.

EUGENE BIRCHWOOD, M.D.

AND

H. GIDEON WELLS, M.D.

CHICAGO

It is a common observation that postmortem examination may reveal extensive atherosclerotic changes in the coronary arteries of the hearts of persons who have shown no marked evidence of myocardial damage during life. This raises the question whether thick atherosclerotic plaques which seem nearly to occlude the coronary arteries when these are seen in the collapsed state at the postmortem examination, really diminish to an equal degree the lumen of the artery when it is distended with blood under the usual intravascular pressure. The classic observation of Thoma¹ convinced him that atherosclerotic plaques in the aorta really did not protrude into the lumen but merely filled in bulgings resulting from weakness of the media. He made paraffin casts of the aorta at blood pressure and reported that the plaques which bulge into the lumen after death are really ironed out during life when the aorta is filled under the usual tension of the blood pressure. He therefore considered arteriosclerotic plaques as patches which fill in the depressions resulting from focal weakening of the wall. Attempts have been made to repeat this work particularly by Ophüls² in 1906 and Klotz³ in 1910 who obtained negative or unsatisfactory results and could not confirm Thoma's observations on the aorta.

Thoma's conception of the development of arteriosclerosis with primary medial changes and secondary atheroma formation is supported by some investigators notably Beitzke,⁴ and it has often been pointed out that in the coronary arteries the media is usually found to be thinner under sclerotic plaques than elsewhere, although it has not been determined whether the plaque formation is primary or secondary to the medial condition. Many students of atherosclerosis consider the intimal changes as primary (Duguid,⁵ Klotz⁶ and Ophüls⁷), but the exact nature of the process has not yet been determined. Regardless of the primary or secondary nature of the plaques they seem to narrow the lumen of the dead arteries, but whether they do so in living hearts has not been determined. A great volume of work has been published on coronary arteriosclerosis and we do not wish to add needless or purposeless material but as we have not found a comparative study of the caliber of the vessels at blood pressure and in the collapsed postmortem state we venture this brief report.

In order to determine the configuration of the lumen of the coronary arteries under living conditions, they were examined roentgenologically when distended with an injection mass of a suspension of barium sulphate, tragacanth and water. Fresh hearts of persons old enough to exhibit coronary atherosclerosis of varying degrees were washed in physiologic solution of sodium chloride and the coronary arteries perfused with the radiopaque solution. The coronaries were then filled with the opaque suspension and thus held at mean aortic pressure while stereoroentgenograms were taken in the roentgenologic laboratory of the University of Chicago Clinics under the direction of Dr Paul C. Hodges. The pressure was then released and the heart

the roentgenogram shows well filled vessels with smooth contours and only minor points of narrowing, while the arteries themselves when sectioned show what seem to be very obvious points of narrowing at the sites of plaque formation. These differences are listed in the table and are particularly evident in hearts 1, 2, 4, 5, 6 and 9. (Note the parallel columns of figures for cross section and X-ray narrowing and vessel caliber.) The number of points of apparent narrowing seen on cross section are numerous despite the fact that the roentgenograms of the same arteries when acted on by the normal expansive force of the blood pressure show them to have had a practically uniform lumen without noticeable constriction. The

fixed in solution of formaldehyde. After a small series of these hearts had been collected and such plates prepared, the coronary arteries were examined by the usual necropsy methods and rather striking differences were found between the apparent effect of atherosclerosis as seen in the collapsed artery and the real condition of the lumen. The coronaries were sectioned coronally at intervals of from 2 to 3 mm and the lumen was measured directly with a millimeter rule. The roentgenograms were taken at 27 $\frac{1}{16}$ inches, 60 kilovolts, 100 milliamperes, and 1 second exposure. There is some slight distortion of the image in such plates but this is far overshadowed by the variations recorded in the accompanying table.

The examination of the roentgen shadow and the gross material brings out certain very evident differences of caliber and contour. In the majority of cases

discrepancy is marked in certain instances, for example the figures for the right coronary artery of heart 1 show a decrease of caliber of the lumen of the collapsed artery to one-half or one-fourth that of the distended artery, except at one point, where it is three-fourths. Similar conditions obtain in the left coronary of heart 2 and the right coronary of heart 4. Rather extreme variations are found in both coronaries of heart 5, but particularly in the left, where in the cross section the lumen is pinpoint, or about 0.2 mm, and in the roentgenogram it is of the usual caliber, or 3 mm in diameter. Looking at the cross section of this artery as exhibited at the postmortem examination, it would appear that the blood flow at this point would have been greatly reduced, whereas the artery really had an adequate lumen, the same size here as elsewhere. Not all points of narrowing are listed and

the figures are not absolute, as precision instruments were not used. Those given certainly substantiate the very obvious differences seen between the x-ray caliber at mean aortic pressure and the gross caliber seen in the undistended artery.

A more graphic representation of the conditions is furnished by the accompanying illustrations. Figure 1

Fig 1—Heart in case 4 with the arteries distended under mean systolic pressure. The lumen of the large arteries is seen to be practically uniform despite the fact that their walls exhibited many sclerotic plaques which seemed to constrict them at many points.

shows the x-ray appearance of the heart in case 4. It will be seen that the cast of the lumen of the large coronary vessels indicates that the lumen is practically uniform throughout and gives no indication that there is anywhere any appreciable constriction by the numer-

Fig 2—Drawn outline of the lumen of the coronary arteries in case 4 with exact reproductions of cross sections of the artery walls at various levels. It is seen that the lumen is quite free from constriction at levels where the artery walls are much thickened by sclerotic plaques.

ous atherosclerotic plaques that were present in the walls of these arteries.

Figure 2 is a drawing outlining the lumen of the injected coronary arteries of this heart, with exact reproduction of cross sections of these arteries at these points, made from photographs of the stained cross

sections. It will be seen that marked variations in the thickness of the artery walls at different levels, and apparent marked constrictions in the lumen, are not associated with any appreciable constriction in the artery when distended by mean systolic pressure.

Figure 3, a roentgenogram of an injected heart, shows that when a coronary artery is really occluded the method of injection used brings out the presence of the obstruction.

Surely, in the light of these rather marked variations in size and contour of the coronary arteries when distended and when collapsed, one must take into consideration the postmortem collapse of arteries in evaluating changes observed post mortem and realize that arteries with apparent narrowing on cross section may not really have been narrowed during life. This is particularly true in instances in which the plaque involves only a small portion of the circumference of the vessel. Fundamentally, these results on a small number of hearts seem to support the view of Thoma

Fig 3—Coronary vessels of a heart with fatal occlusion of right coronary artery showing that the method used demonstrates the presence of actual obstruction (case 9).

that atherosclerotic plaques fill defects in locally dilated vessels and may not encroach on the lumen, at least not to the extent that the postmortem appearance suggests. We would call attention also to the fact that large atherosclerotic portions of vessels when calcified, so that they form rigid casts of the vessels, always present a concave surface toward the lumen, showing that they have not encroached on the lumen during life. These natural casts are equivalent in significance to the original experimental casts made by Thoma.

SUMMARY

A small series of hearts has been examined to determine the relation between the size of the lumen of the coronary arteries at the site of atherosclerotic plaques, as seen in the collapsed artery in the usual postmortem examination, and the true size of the lumen when the artery is distended by the usual blood pressure. The results of this preliminary study indicate that coronary arteries exhibiting many atherosclerotic plaques which,

as seen at postmortem examination seem to cause marked local constrictions may when distended by the usual blood pressure possess a fairly uniform lumen without evidence of constriction. Apparently the atherosclerotic plaques in coronary arteries do not necessarily protrude into the lumen during life, and the apparent narrowings seen in the dead body may not have existed during life.

Clinical Notes, Suggestions and New Instruments

PRIMARY REPAIR OF SEVERED PAROTID DUCT METHOD OF FIXATION OF AN INLYING DOWEL

CHARLES G. BROHM, M.D. and CLARENCE E. BIRD, M.D.
LOUISVILLE, KY.

Since 1926 there have appeared three articles¹ emphasizing the importance of the immediate repair of severed parotid ducts. Disfiguring and annoying external parotid fistulas are prevented by this procedure. Such fistulas, as is well known, are often difficult to close. All these authors have recorded successful cases. Tees, two Dickinson one and Black and Flagge one, four in all. The literature previous to 1926 is strangely silent on the subject of primary anastomosis, most discussions and case reports even those which appeared during and shortly after the World War concerned themselves with problems of secondary repair and with the control of the discharge. Because the war wounds were ragged, extensive and contaminated it was impracticable for the most part to attempt primary suture. Nevertheless, Schmieden² in 1916 reported the primary end-to-end repair of a severed duct on the field of battle, no particulars as to technic were included in his short note.

The authors of the recent articles have been confronted with fresh, reasonably clean wounds in which the ducts had been

Fig 1—Diagram showing filiform bougie used as a dowel over which the parotid duct severed in two places was sutured. The filiform was passed out through the cheek and sutured to the skin.

severed sharply somewhere in their masseteric portions. In the cases of Tees a strand of catgut was inserted into the severed ends, where it served as a dowel (Tees) over which the duct

was approximated by means of two fine interrupted catgut sutures passed through the sheath. In one case the oral end of the catgut strand was left hanging out of the opening of Stensen's duct into the mouth; no fixation was used. In the other instance the short piece of catgut was left entirely within the duct and it is this arrangement which the author advises.

Fig 2—Five months after primary repair of severed parotid duct.

Dickinson utilized a strand of silkworm gut which was allowed to project into the mouth. He then fixed the silkworm gut at its point of entrance into the mouth by a suture. However the strand fell out into the mouth two days later. Black and Flagge used a small ureteral catheter as a dowel and cut it off leaving about one inch extending outside the duct into the mouth. The method of fixation as described in a recent letter from Dr. Black³ was by means of two or three interrupted linen sutures passed through the buccal tissues at the orifice of the duct and tied around the catheter. The catheter remained in position until it was removed on the ninth postoperative day. In his letter Black mentioned a subsequent case of primary repair and also one of secondary suture in which an external fistula had been present for two and one-half months. In both instances he used the technic described in his published case with perfect results.

An interesting case of secondary repair forty one days after injury to the duct is reported by Butler and Guinan.⁴ Their technic included the use of a ureteral catheter, as in Black and Flagge's case, but they anchored it to the canine tooth of the upper jaw with a silk ligature, a technic familiar to oral surgeons.⁵ Whenever the lower jaw moved, the catheter slipped back and forth through the duct for about 0.5 cm.⁶ Butler feels that the motion is advantageous, provided the catheter is inserted far enough into the duct to prevent its tip from punching out between the sutures at the anastomosis. He removed the catheter on the third day, feeling that possibly there might be sufficient swelling, with the catheter in place, to obstruct the duct.

In the following case a filiform urethral bougie was anchored by passing it from the mouth out through the cheek and suturing it securely to the skin at the point of exit.

March 10, 1934, W. M., a man, aged 22, was cut deeply with a sharp knife across the left cheek. The wound extended in an upward curve from a point 1 cm above and slightly medial to the corner of the mouth to a point 2 cm in front of the lobe of the ear. Under procaine infiltration anesthesia the cleanly incised tissues were washed thoroughly with warm saline solution and all bleeding points were tied with fine plain catgut. On inspection of the wound it was found that the parotid duct had been severed twice, thus isolating the short segment of the structure that curves sharply around the anterior border of the masseter muscle. The knife had passed deeply into the buccinator and anterior portion of the masseter muscles, but the wound was more superficial posteriorly and the parotid gland was uninjured.

A filiform bougie was cut in two and the blunt end of the small half was passed into the mouth through the distal portion of the duct. The smooth tip was threaded back through the isolated segment and into the remainder of the duct to the level of the gland. The anastomoses were then accomplished with interrupted split silk passed through the sheath on small French eyed needles. The sheaths of the muscles were united with fine chromic catgut sutures, the deep layer of the superficial fascia with fine plain catgut, and the skin with silk. No drainage was used.

Attention was now turned to the problem of anchoring the filiform bougie. Inspection of the oral mucous membrane showed a small rent about 1.5 cm anterior to the parotid opening. The filiform was cut off to a proper length inside the mouth and the end was passed through this rent to make its appearance through a nick in the skin halfway between the vermilion border of the lip and the ala nasi. It was securely fastened to the skin by a silk suture (fig. 1).

The wound healed by first intention and the sutures and filiform bougie were removed on the seventh postoperative day. Clear saliva was observed to flow from the opening of Stensen's duct at that time and continues to do so at present five months after operation. There has been no pain or swelling in the region of the gland. The scar of the main wound persists but it is impossible to detect the point of exit of the filiform bougie (fig. 2). There is no demonstrable weakness of any of the facial muscles.

The principles of the primary anastomosis of Stensen's duct appear to be established: (1) Repair the duct as soon as possible after the injury (certainly within eight hours); (2) use care in hemostasis; (3) insert a small ureteral catheter, a filiform bougie, a strand of silkworm gut or any other firm, pliable, sterilizable material which will not swell which may be made to act as a dowel and seton and which may be anchored in place; (4) suture the sheath of the duct over this dowel with fine interrupted silk or catgut, and (5) close the wound anatomically without drainage.

The only feature that appears to offer any difficulty is the matter of fixation of the dowel. It seems to us important that the dowel should be under control and that it should not come out prematurely. Whether or not it has a lumen is of no consequence (Dickinson), since most of the saliva will pass down between the mucous membrane and the dowel anyway, but there would be considerable likelihood of obstruction to the duct by collections of blood, leukocytes and serum and from pressure due to swelling of the cheek if the supporting dowel should not be in place during the first four or five days. Leakage at the suture line leads to collection of saliva outside the duct, which after removal through the skin of the cheek by means of a needle and syringe, may or may not result in a cutaneous fistula. In a controlled incising dowel there lies safety.

The two methods of choice for the fixation it seems to us are, first to tie the dowel to a tooth or, second to pass it through the cheek and suture it to the skin. It might be objected that the latter method opens up fresh tissues to the possibility of infection. However, the dowel acts as its own drain and the likelihood of complications from this source is we are sure remote. The point of exit of the dowel through the skin leaves little or no trace after the tiny crust comes off. For an edentulous individual or for a child or adult who will be troubled by the end of the dowel in the mouth, the plan of exteriorization and suturing to the skin is preferable. A stitch passed through the opening of Stensen's duct and tied about

the dowel cuts through rapidly and does not provide certain fixation. The stitch in this position also results in local edema and a tendency toward obstruction to the flow of saliva. The dowel should lie freely in the duct as in the two methods of fixation which are recommended.

SUMMARY

The principles of primary repair bear repeating: (1) Operate as soon as possible after the injury; (2) use care in hemostasis; (3) insert a small ureteral catheter, filiform bougie, a strand of silkworm gut or any other firm, pliable, sterilizable material that will not swell, which may be made to act as a dowel and seton and which may be anchored in place; (4) suture the sheath of the duct with fine, interrupted silk or catgut, and (5) close the wound anatomically without drainage.

Fixation of the dowel is important and is best accomplished either by, first, tying it with silk to the upper canine tooth or, second as we have suggested, passing it through the cheek and suturing it to the skin.

PROSTATIC HYPERTROPHY

CLINICAL LECTURE AT CLEVELAND SESSION

N. G. ALCOCK, M.D.

IOWA CITY

The subject of treatment of hypertrophy of the prostate can be reduced to very simple terms by putting down at the outset the three following statements as facts and letting them form a basis for a discussion. I doubt whether there will be any one who will dispute them:

1. The enlarged prostate produces trouble only when it causes obstruction at the bladder neck.

2. The degree of obstruction is not in relation to the size of the gland but rather to the location and arrangement of the enlarged portion.

3. Obstruction is caused not by the entire enlarged portion but by enlargement in certain localities and certain directions.

In figure 1 is shown a cystogram of an enormously enlarged prostate that is causing the patient no trouble whatever while figure 2 shows a comparatively small gland that is producing almost the maximum trouble.

If the foregoing statements are true, it follows that the solution of the prostate problem is (1) to overcome bladder neck obstruction and (2) to restore as nearly as possible bladder function.

In any type of prostate surgery, not all the results are perfect even though the patient lives. Frequently some of the damage caused by the obstruction is permanent, and even though the obstruction is relieved and bladder function reestablished this permanent damage remains. Furthermore, surgery of the prostate is in a way plastic and in any plastic surgery on any organ instituted to reestablish function there will be varying degrees of perfection in the results. Therefore common sense indicates that not all the results of prostatectomy or resection will be perfect.

There are four methods of overcoming bladder neck obstruction:

1. The use of the urethral catheter either by intermittent catheterization or by the indwelling catheter. This overcomes the obstruction by putting a siphon over the dam but at best it is only temporary and it does not restore normal bladder function.

Read before the General Scientific Meeting at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 11, 1934.

2 The permanent suprapubic drain overcomes the obstruction by diverting the flow of urine through a new channel but it is inconvenient and unsatisfactory and more or less temporary and does not restore bladder function

These two methods can be used temporarily to overcome the obstruction and to repair temporary damage that the obstruction has produced. These are the essential features of all preoperative treatment

3 Surgical prostatectomy, either suprapubic or perineal solves the problem by removing all the enlarged or hypertrophied

Fig 1—Prostatic hypertrophy. Patient aged 77 complained of pain in the lumbar region when doing heavy work. Family physician found a very large prostate on rectal examination and raised the question as to the prostate being the cause of the pain. No nocturia. No day frequency. No difficulty. Good stream. No residual. Urine normal. Kidney function normal. Prostate by rectum and by cysto-urethrogram shown to be very large but was producing no obstruction and therefore no operation was indicated. Back pain explained on basis of arthritis

portions of the gland. It overcomes the obstruction and it restores bladder function

So much has already been written about prostatectomy that no further discussion of that particular subject is needed here

4 Transurethral prostatic resection on the other hand, solves the problem first by determining accurately what portion, or

Fig 2—Prostatic hypertrophy in patient aged 67. Symptoms of bladder neck obstruction for two years. Much difficulty and frequency and residual urine of 500 cc loaded with pus. Prostate by rectum comparatively small and not more than a 1 on scale of 1 2 3 4. Cystogram and urethrogram (A and B) show small intravesical median lobe with typical and marked deformity of the bladder neck and prostatic urethra. Here is a very small degree of hypertrophy causing almost the maximum degree of obstruction. Resection indicated and done with satisfactory result.

portions of the gland are causing obstruction, and, secondly, by removing accurately only those portions. It overcomes the obstruction and it restores bladder function

The explanation of the recent popularity of transurethral prostatic resection is simple. An instrument that will enable the operator to determine accurately

what portion, or portions, of the gland are causing the obstruction and to remove accurately only those portions must be one that gives the operator (1) good vision, (2) facility to control hemorrhage perfectly, and (3) to remove accurately an adequate amount of tissue."

The Stearns-Davis resectoscope was the first instrument that approached these requirements, and the Stearns-McCarthy instrument is an improvement on the Stearns-Davis

There are two things that have made transurethral resection possible. Different lens systems have been adapted to the resectoscope, so that excellent vision is possible. Second, there have been developed high frequency machines that give currents that will control hemorrhage and cut tissue

Good vision with the resectoscope is possible. By means of the three lens systems—foroblique, the indirect and the retroversion—the gland can be viewed

Fig 3—Prostatic hypertrophy in patient aged 84. Symptoms for five years. Complete retention ten times. Catheter almost daily for eight weeks. Residual urine 700 cc loaded with pus. Advanced arteriosclerosis. Very weak and feeble old man. Poor renal function. Very poor operative risk. Very large 3 prostate by rectum. Cystogram and urethrogram (A and B) show very large intravesical median and lateral lobes with considerable intraurethral enlargement of the laterals. Resected and 30 Gm of tissue removed. C and D show cystogram and urethrogram twelve days after resection. Note the absence of the filling defect at the bladder neck and the change in the prostatic urethra. At this time the patient was voiding easily and without difficulty and with residual urine of less than 15 cc. Much less pyuria

from every possible angle and direction. This observation when combined and coordinated with the accurate results of examination by means of the preoperative air cystogram and the urethrogram with jelly made of iodized oil gives one even a more accurate idea of the topography of the bladder neck and prostatic urethra than one could possibly get with the bladder cut wide open in front of one. This excellent vision plus experience—and I emphasize experience—enables one accurately to size up the situation and determine what portion or portions of the gland are causing the obstruction and, therefore, what tissue must be removed. This excellent vision plus the adequate high frequency

current enables one to make every cut with the greatest degree of accuracy to control all bleeding as one goes along, and to do the entire operation under the eye.

I doubt whether there are any who will dispute the statement that it is now pretty well established that the modern resectoscope does give one the means of doing accurately what one is supposed to do with it.

The first question that arises is this: How much tissue should be removed? This is easy to answer: the part or parts that are causing the obstruction should

Fig 4—Prostatic hypertrophy. The patient aged 97 had symptoms for ten years. Complete retention many times. Residual as high as 1000 cc. Catheter daily for four weeks. A and B are the cystogram and urethrogram before resection. Note the quite large intravesical median lobe and the very large intraurethral lateral lobes. Resected at three sittings, not one of which was more than twenty-five minutes in duration. 56 Gm of tissue removed. C and D are the cystogram and urethrogram three days after the third resection, at which time there was complete relief of the obstruction. Patient voided easily and without difficulty and without residual. Note the change at the bladder neck and in the prostatic urethra.

be cut away. In some prostates this requires the removal of only a small amount of tissue while in others it may mean a considerable amount.

At this point it might be well to ask this question: How much does the average hypertrophied prostate that is removed surgically actually weigh? These prostates vary greatly in size. A gland the size of a golf ball weighs 43 Gm, one the size of a hen's egg weighs 51 Gm, one the size of a lemon weighs 140 Gm, and one the size of an orange weighs 314 Gm. In the records of my own prostatectomies the weight of the gland removed was recorded in each of 433 cases, the largest was 270 Gm and the average weight of the 433 was 38.3 Gm. Therefore, if with the resectoscope one removes from 15 to 35 Gm one is removing a very large part of the average gland. In 85 per cent of the first hundred cases that I did by the resection method I removed less than 10 Gm of tissue, in the last hundred—the eighth hundred—more than 10 Gm was removed in 90 per cent of the cases, and in only 2 per cent was less than 5 Gm removed. I know from my experience that it is absolutely essential to remove an

adequate amount of tissue and I find as my experience has grown that I am removing larger and larger amounts of the gland. The largest amount removed at one sitting was 54 Gm, the largest amount removed from one patient was 134 Gm in three sittings. In the bulk of the cases now being done, from 15 to 35 Gm is removed. Usually it is not particularly difficult with experience to remove from 25 to 40 Gm at one sitting. In the beginning the time consumed at a resection was from an hour and a half to two hours and a half. At present the patient is seldom kept on the table more than fifty minutes and in the average case the resection is completed in from twenty to twenty-five minutes. In general it may be said that from one third to three fourths of the gland is removed.

Figures 3, 4 and 5 represent preoperative and post-operative cysto-urethrograms in cases in which resection has been done and an inspection of these pictures I think will demonstrate that adequate amounts of tissue can be removed.

The tables give the results in numbers and percentage of 600 consecutive resection cases and 600 consecutive prostatectomies that I have done myself. This is simply a repetition of the tabulated results that I presented before the American Medical Association a year ago with the addition of 200 cases, and these tables add nothing to what the former ones showed. These 600

Fig 5—Prostatic hypertrophy. The patient aged 80 had symptoms for eight years. Complete retention eight times. Catheter four times daily for six weeks. Gross hematuria with clots for four weeks. Much loss of blood, hemoglobin 50 per cent. Much pyuria. Condition very poor. The preoperative cysto-urethrogram (A and B) shows an enormous intravesical median lobe with almost as much intraurethral enlargement of the laterals. Resected in three sittings at six day intervals with removal of 33, 51 and 50 Gm respectively, a total of 134 Gm. C and D represent the cystogram and urethrogram eight days after the third resection. Note that the intravesical median lobe is gone and that the prostatic urethra is large and straight. Patient voids easily and freely. Residual 50 cc and four days later there was none. Only slight pyuria. No hematuria since first resection. Hemoglobin 90 per cent. General condition much improved.

resections are the cases done up to December 1933. Since then 200 additional cases have been added to this list. Again I wish to emphasize the fact that in this

series there has been no selection of cases and that it does not include bars, contractures and small median lobes, or so called prophylactic prostatectomies. In every one of these 600 cases I would have formerly recommended a prostatectomy. There is this difference, however, even in these two series. It will be noted that the average age of the prostatectomy patients was 66,

TABLE 1—General Summary

	Number		Percentage

Hospital days	10.3	71.4		
Deaths	23	134	4.0	22.3

while that of the patients in whom resection was done was just about 73, and if I should add to this list the additional 200 cases that I have done since this table was made it brings the average age of resection patients to over 73 years. The average age of any series of prostate patients is quite a fair index as to the operative risk of the individual patient. It will be noted that 63 per cent of the resection patients were over 70 years of age and that only a very small percentage of them were under the age of 60. It has been my observation that there are very few men under the age of 60 who really need a prostatectomy or a prostatic resection. The youngest patient was 55 and the oldest 97.

The second thing that stands out is the difference in hospitalization. The prostatectomy patients were in the hospital for an average of seventy-one days, the resection patients were in for an average of sixteen and a fraction days and this sixteen and a fraction days includes the preoperative and postoperative period and it covers the entire period that these patients are under our observation. When they come to us they go immediately into the hospital and when they leave the hospital they leave us entirely and go back to their home physicians.

The third thing to which I wish to call attention is the difference in the mortality rate. In the prostatectomies the mortality rate is 22.3 per cent, while in the resections it was 4.6 per cent. It has been said that this 22.3 per cent mortality for prostatectomies is scandalous and I will admit the allegation, and yet when one considers that the bulk of these cases were in the charity service it is well within the range of the mortality rate that goes with prostatectomies in similar services and, in fact, it is lower than that reported from several charity services. Furthermore, I believe that 20 per cent is nearer the mortality rate of prostatectomies the country over than is the rate that is found in series reported in the literature. I have also shown that by the manipulation of figures such as dropping out those who died following the first operation and also dropping out the carcinoma cases, this 22.3 per cent mortality could be reduced to something like 5 per cent, but there is only one way of determining mor-

talidity, and that is the question as to whether the patient is alive or dead. In the resection cases the mortality rate in the first hundred cases was 15 per cent. Not all of these deaths were due directly or indirectly to the resection but the patients died just the same. As experience has grown it will be noted that the mortality rate has consistently dropped. For the additional 200 cases done since this tabulation was made, the mortality rate is less than 2 per cent. The mortality rate for the last 500 cases done is 1.4 per cent and the average age of the dead patients in this group is over 78 years.

These tabulations give the results that can be set down in numbers and percentage but they do not give the true picture either pro or con. I believe that the only true picture that one can get of the difference in these two methods is that which one sees in his every-day experience in the hospital wards. I cannot put down in tabulated form or even in words the vast difference in the pictures of the two situations—all in favor of resection. I am convinced that resection carries with it much less risk to the patient and gives immediate postoperative results that are as good if not much better.

What then, are the ultimate results? There are two things that stand out against resection: one is infection and the other pertains to functional result.

Infection is a much more common condition following resection than following prostatectomy. I think that no one will dispute that. In my patients that have died infection has played the major role. Hemorrhage has had nothing whatever to do with any mortality. But even with this bad element the patients do get well. And a mortality of 1.4 per cent for the last 500 does not speak for the severity of this infection.

In the beginning, one of the most disturbing features in the functional result was the distressing frequency

TABLE 2—Mortality

of urination that many of these resection cases showed. In practically all of them there was considerable of it immediately following the operation and in many it continued for weeks and months. In some of these earlier cases it was so great that I considered the results very unsatisfactory but in a vast majority of them the condition eventually disappeared. In some of them the removal of additional tissue corrected it. In the later

cases, and particularly since I have been removing larger and larger amounts of tissue, this phenomenon has been of minor importance. All in all it is quite insignificant.

I do not doubt that some of the patients in whom I have performed resection have had, or will have, prostatectomies. I know of only one so far who has had his prostate removed. I do not doubt that if I could follow every one of them I would find probably several who have had this experience. Several of the earlier patients have returned for additional resection but I do not feel that this is anything against resection because I am conscious of the fact that at least the first 200 cases were not done as well as they might have been done. I do not doubt that some of the patients who are now being operated on and operated on well will come back later on for additional resection, but I am sure as I watch these cases that the number is going to be very small. Of course, some of them will come back just as some of the prostate patients had to be prostatectomized a second time.

Now the all important question arises as to what cases should be treated by resection and what cases should not. A year ago I said that there were two small groups of cases in which I felt that resections should not and could not be done. One group was those in which the instrument could not be introduced into the bladder. That still holds true, of course. This is a very small group. In a series of over 800 cases there have been five such cases. The second group that I said a year ago was not amenable to resection was those in which the enlargement of the prostate was considerable and was confined to the space between the two sphincter muscles. I believe now that resection can be done in those cases. I am therefore willing to go on record in saying that I believe it is possible to perform resection in any case in which the instrument can be introduced into the bladder.

Whether a man shall do resections or prostatectomies depends entirely on which method gives him the best results, and the only way that he can determine this is by looking his results squarely in the face and being guarded by what he sees and not by what some one else does. Therefore the question of doing resections or prostatectomies is purely a personal one. The results that one gets in resections depend almost entirely on how well the actual resection job is done and this is in turn determined largely by the amount of experience that the operator has had. This is, I think, the most serious drawback to resection. It is a thing that cannot be taught and can be learned only by hard, tedious experience. Therefore, if a man is going to become adept at doing it he must have access to a large volume of material and the number of men who have access to such a large volume of material is comparatively small. Therefore, resection is certainly not the operation for the occasional operator. In my own experience it took at least 200 cases crowded into a comparatively short period of time to teach me how to do them only fairly well.

There is one thing more that might be said. I believe that in the end it is going to be found that the question as to whether resections or prostatectomies are going to be done will be determined not by the general surgeon or the urologic surgeon but by the home physician. He is the man who sees the ultimate and final result and he is the one that is going to determine which of these operations his patients are going to have.

GLANDULAR PHYSIOLOGY AND THERAPY

THE POSTERIOR HYPOPHYSIS

E. M. K. GEILING, M.D.

BALTIMORE

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues of THE JOURNAL. When completed, this series will be published in book form.—Ed

The primary structural elements of the posterior lobe of the hypophysis are the neuroglial cells, the pituicytes and the nerve fibers. The neuroglial cells resemble those found elsewhere in the central nervous system. In the pituitary some of them have become differentiated to form pituicytes,¹ highly branched cells that have granules in the cytoplasm. The presence and significance of nerve fibers in the posterior lobe are still an open question.

ORIGIN AND PATH OF ESCAPE OF THE SECRETION

None of these structures, with the exception perhaps of the pituicytes, are regarded as secreting elements in the ordinary sense.

Many investigators believe that the secretion is formed by cells of the pars intermedia, which envelop and interdigitate the neural lobe to a greater or less extent, depending on the species.² This view is not in harmony with newer studies, which show that extracts from the neural lobe of the chick³ and whale possess pressor, oxytocic and antidiuretic properties, although in these animals the structure of the neural lobe is such that the possible admixture of pars intermedia in the extract is excluded. Another widely accepted hypothesis is that this secretion is derived from the Herring bodies.⁴ These acellular structural elements, irregular in number, size, shape, staining capacity and distribution, are considered to be a secretion antecedent migrating from cellular derivatives of the pars intermedia into the lumen of the third ventricle, hence the alleged presence of posterior lobe secretion in the cerebrospinal fluid. Experiments now in progress throw doubt on the reality of these Herring bodies and indicate that they may be fixation artefacts. These studies tend to show that the neuroglial tissue is infiltrated by a homogeneous stainable material which on fixation is precipitated out in the form of aggregates (Herring bodies). In addition, the most refined assay methods have failed to reveal the presence of the posterior lobe secretion in the cerebrospinal fluid.⁵

The simplest explanation not inconsistent with the facts is that the posterior lobe secretion is elaborated by the intrinsic elements of the lobe itself and enters

directly into the general circulation by the blood channels recently described by Popa and Fielding⁶

It is generally conceded that the cells of the pars intermedia elaborate the melanophore expanding hormone, or intermedin, which is discussed in a separate paper by Professor Zondek⁷

THE CHEMISTRY OF POSTERIOR LOBE EXTRACTS

The active constituents present in posterior lobe extracts, although quite suitable for clinical work, have not as yet been isolated as chemical individuals. Abel and his associates⁸ have isolated a tartrate of high purity possessing pressor, oxytocic and antidiuretic properties. Kamm and his associates,⁹ and more recently Stehle¹⁰ and others, have separated from pituitary extracts two fractions, pitressin and pitocin which have been fairly highly purified. Pitressin has pressor and antidiuretic properties, and some melanophore activity which decreases with purification and is not due to a hormone derived from the pressor and oxytocic principles but to a separate entity elaborated by the cells of the pars intermedia.⁷ Pitocin has mainly oxytocic activity, its other effects are due to impurities. Gulland and Newton¹¹ have succeeded in making very potent preparations of this substance. Many of the problems relating to both the chemistry and the physiologic actions of these substances must await final solution until the "mother substance" of Abel,¹² or the fractions derived therefrom or existing separately,⁹ are obtained as chemically pure compounds. These should be of astounding potency, judging from the high degree of physiologic activity exhibited by impure preparations.

At present there is available an international pituitary powder against which all commercial preparations are standardized. The unit of pituitary is the activity contained in 0.5 mg of standard pituitary powder (U S P X).

PHYSIOLOGIC EFFECTS

Posterior pituitary extract (solution of pituitary, U S P X) exerts striking physiologic actions on the cardiovascular, respiratory and renal systems, on smooth muscle, on certain glandular structures and on the metabolism. The separation of pitressin and pitocin from pituitary extracts necessitated apportioning these multiple pharmacodynamic actions. Pitressin elicits the cardiovascular, respiratory, renal, intestinal and certain metabolic effects, and pitocin the oxytocic action. Both substances (and solution of pituitary also)¹³ cause hyperglycemia and act as antagonists to insulin. Since neither substance has been prepared free of the other, there is some overlapping of the physiologic effects that they produce.

CARDIOVASCULAR AND METABOLIC EFFECTS

In man, therapeutic doses of either solution of pituitary U S P or of pitressin given intramuscularly or subcutaneously do not cause any significant rise of blood pressure in spite of the marked pallor, which would lead one to infer that the arterial tension is elevated.¹⁴ There is a decided but brief fall in pulse rate, oxygen consumption and cardiac output, which is followed by a more prolonged rise.¹⁶ Pitocin causes only a slight increase in oxygen consumption and negligible changes in the circulation. The decreased cardiac output after solution of pituitary and pitressin may be due to a reflex initiated by the threatened increase in blood pressure that would result from the constriction of the cutaneous vessels. The subsequent elevation in cardiac output and pulse rate is due to the accumulation of catabolites during the period of decreased oxygen consumption after administration of these drugs. This accumulation of catabolites causes a condition of "oxygen debt," the liquidation of which is manifested in a later increase in oxygen consumption (chart 1).

In trained unanesthetized dogs the effects of these drugs in larger doses per kilogram of body weight

Chart 1—The effect of an intramuscular injection of 0.4 cc of pitressin into a normal man. The pulse rate and cardiac output are decreased below the normal for a brief period followed by an increase of more prolonged duration. Similar changes occur in the oxygen consumption except that both the decrease and the increase are more prolonged than in the case of the cardiac functions.

given intravenously, are more intense but essentially similar to those found in man, except for the blood pressure.¹⁵ For a brief period the venous blood approaches an arterial character, owing to the failure of the body to take up oxygen, during this period the oxygen consumption falls markedly, lactic acid accumulates in the tissues (chart 2) and there is a diminished blood flow,¹⁷ as measured with a modified Reim stromuhr.

The blood pressure response in experimental animals to solution of pituitary and to pitressin is determined by several factors such as dosage, time interval between injections, type and depth of anesthesia and species of

CLINICAL USES

Conservative obstetricians restrict the administration of posterior pituitary preparations largely to the treatment of postpartum hemorrhage and to cases of incomplete abortion in which repeated moderate doses (0.5 cc) frequently bring about spontaneous completion. Pituitary extracts are employed at times for the induction of labor, for example, intranasal application or the cautious use of small intramuscular doses following the administration of castor oil and quinine, the latter procedure however, is occasionally fraught with danger to the child. Intranasal applications are often an aid in producing satisfactory uterine contractions in cases of primary or secondary inertia. It is the practice in many clinics to use solution of pituitary intramuscularly immediately after the birth of the child to hasten separation of the placenta and to decrease bleeding during the third stage. Such a procedure, however, may produce an hour-glass contraction of the uterus and thus increase the incidence of manual removal of the placenta. In rare cases intramuscular injections of the drug will not overcome atony and in such instances excellent results are obtained by the intravenous use of from 3 to 5 minims (0.2 to 0.3 cc). No significant alterations of blood pressure or other untoward effects following solution of pituitary intramuscularly have been noted in the obstetric clinic of the Johns Hopkins Hospital and hence its use seems safe in the toxemias of pregnancy. In addition, no clinical advantage resulted from the employment of pitocin, in fact in the Hopkins clinic stronger contraction of the uterus was elicited with solution of pituitary than with pitocin. Contrary results are reported from other clinics.

Solution of pituitary and pitressin are also employed to allay postoperative abdominal distention and in the treatment of diabetes insipidus. Posterior pituitary preparations may also be used to overcome the effects of an overdose of insulin, since the two are antagonistic.

DISEASES AScribed TO HYPERSECRETION

In recent years, attempts have been made to explain some of the baffling and serious diseases such as the toxemias of pregnancy, especially eclampsia, and angina pectoris, on the basis of an excess secretion by the posterior lobe.²⁸ The data on which these claims rest are not very convincing and more recent experiments have not substantiated the earlier work.²⁹

CONCLUSION

It seems that in spite of the huge volume of work on the posterior lobe secretion one cannot assign with certainty any specific physiologic role in the animal economy to this potent autopharmacologic agent. Possibly the pressor component acts as an efficient regulator of the exchange of metabolites between the blood and the tissues (capillary hormone) and exercises a renal function, and the oxytocic portion may function during parturition to quicken and render more effective the uterine contractions, which result in the expulsion of the products of conception.³⁰

Therapeutics

THE THERAPEUTICS OF THE COOK
COUNTY HOSPITAL

EDITED BY BERNARD FANTUS, MD
CHICAGO

NOTE—In their elaboration, these articles are submitted to the members of the attending staff of the Cook County Hospital by the director of therapeutics, Dr. Bernard Fantus. The views expressed by various members are incorporated in the final draft for publication. The articles will be continued from time to time in these columns. When completed the series will be published in book form.—Ed

THERAPY OF FUSOSPIROCHETOSIS (FUSO-
SPIRILLOSIS)

Correct diagnosis is of great importance, because treatment is almost specific. Two special localizations of the infection are discussed here: oropharyngeal and bronchopulmonary. For localization on genitals, see Therapy of Chancroid and Bubo.

OROPHARYNGEAL FUSOSPIROCHETOSIS (VINCENT'S ANGINA,
VINCENT'S STOMATITIS TRENCH MOUTH)

Diagnosis—Single or multiple, grayish white, foul smelling, necrotic patches are present in the mouth or throat, which are easily removed, leaving a bleeding ulcer with a characteristically slight zone of redness and usually little or no glandular reaction in the neck. The feeling of general well being is often in marked contrast to the local pathologic changes. Glandular involvement and fever may however, be present. The condition must be differentiated from diphtheria and syphilis, also from scurvy, granulopenic angina and mercurial stomatitis. It accompanies sprue or psoriasis.

The finding of the spirilla and fusiform bacilli easily stained by basic dyes, such as gentian violet, is not conclusively diagnostic, because such organisms occur in any dirty mouth. They are constant in pyorrhea pockets. They may therefore be found in diphtheria and in any other of the conditions requiring differentiation. Hence the absence of the characteristic manifestations of the diseases with which it may be confused is important for diagnosis.

Prophylaxis—1 As this is clearly a communicable disease, commonly conveyed by eating and drinking utensils, proper disinfection of these and daily mouth hygiene as well as dental asepsis are mandatory. Soap has a definitely spirillicidal effect, hence its presence in a dentifrice is of prophylactic value.

2 Improvement of general resistance is also of prophylactic as well as curative importance, because Vincent's spirochetes are probably pathogenic for man only when either local or general resistance is low.

Treatment—1 Oxidizing agents are efficient because lowered oxygen tension is a necessary factor for the development of these anaerobic organisms.

(a) Solution of Hydrogen Dioxide, diluted with an equal amount of warm water, should be used for the removal of the necrotic tissue and for exposing the infected area to direct treatment with any other agent.

(b) Sodium perborate made into a thick paste with water is spread over the ulcerated area and all over the teeth and kept in the mouth for about five minutes, then the mouth may be rinsed with warm water. While

the patient may be trained to do this, results are more reliable when the treatment is carried out by the physician. In addition, a 2 per cent solution of sodium perborate may be used as a mouth wash and gargle three times daily or even every hour. Sodium perborate is especially useful in the milder cases. Its solution must always be freshly prepared.

Sodium Perborate Aromatized

Glucose	0.01 Gm
Oil of peppermint	0.60 cc
Sodium perborate	30.0 Gm

M. Label: Teaspoonful or two in tumblerful of warm water as mouth wash or gargle.

(c) Chromium trioxide may be employed as an alternative office procedure, for use most especially in the severer cases. Seven per cent solution of chromium trioxide is applied to the ulcers by means of cotton pledgets on stainless foil carriers, after the ulcers have been cleansed by hydrogen dioxide and dried and the mouth has been packed with gauze or cotton rolls. The chromic acid solution is permitted to dry, and the surface is covered with Compound Tincture of Benzoin, which retains the chromic acid in place for a longer time. A simpler method is to place crystals of chromium trioxide on the ulcers and then to give the patient a mouthful of Solution of Hydrogen Dioxide, which reacts with the chromium trioxide, forming a black substance that soon decomposes into chromic acid and nascent oxygen.

2 Nearsphenamine displays its spirillicidal powers in this disease so definitely that it may be used alone or as a succedaneum to one of the foregoing methods. After cleansing with Solution of Hydrogen Dioxide and careful removal of the oxidizing agent and drying, a 10 per cent solution of nearsphenamine in glycerin is thoroughly applied to the raw surfaces by means of cotton applicators once or even two or three times daily. It should remain in place for a few minutes before the patient is permitted to rinse his mouth. There is no harm in swallowing the excess nearsphenamine. The glycerin solution keeps well. In the intervals between applications, the patient may use 2 per cent sodium perborate solution every hour.

If the condition proves obstinate, 0.3 Gm of nearsphenamine may, in addition, be injected intravenously at intervals of several days. In children, a daily dose of acetarsone (one fourth of the 0.25 Gm tablet daily) dissolved in a tablespoonful of milk or of water is reported to give satisfactory results. For adults, one and one-half tablets daily are advocated.

Surgical work in the mouth, even scaling and polishing of the teeth should not be undertaken until the acute symptoms have subsided.

General Therapy—Smoking should be interdicted and a vitamin rich diet insisted on. Cathartics and analgesics may be administered as required.

BRONCHOPULMONARY FUSOSPIROCHETOSIS

Diagnosis—In cases of cough with rather copious greenish brown expectoration possibly blood tinged and generally foul smelling, which may resemble that of tuberculosis or pulmonary abscess, the microscopic examination of the sputum (preferably collected by means of the bronchoscope so as to be uncontaminated by mouth secretion) will make the diagnosis of the type of infection, whose localization may be determined by physical and roentgen examination as bronchial or bronchiectatic pneumonic abscess, or gangrene.

Prophylaxis—Oral hygiene should be employed.

Treatment—1 Arsphenamine. The importance of the early recognition of this variety of infection lies in the fact that early cases respond to intensive arsphenamine therapy (see Therapy of Syphilis). Chronic lesions, especially if the abscess has acquired a fibrous capsule, are very stubborn.

2 Peroral Pulmonary Drainage. (a) As coughing acts as a powerful ally to ciliary action in drainage of the bronchial tract, nothing is more pernicious than to check it by means of opiates, including, of course, codeine, which should never be prescribed in any productive cough. An abundance of fluid and of an alkaline expectorant (see Therapy of Cough) is, on the other hand, likely to be helpful.

(b) Postural drainage is carried on by having the patient assume a head-down posture two or three times daily and accompany this by deep respirations, which are likely to provoke productive coughing. The patient selecting the times for this treatment when he feels the greatest inclination to cough. It might save him a great deal of coughing in the intervals, as well as favor healing.

(c) Bronchoscopic aspiration, at intervals of possibly a week or less, is likely to be a powerful adjunct.

3 Surgery. External drainage of suppurative foci may be considered in suitable cases of nontuberculous suppuration resisting the faithful use of the other methods of treatment. While pneumothorax and phrenicectomy have a large field of usefulness in suitable cases of pulmonary tuberculosis, they should generally not be applied to nontuberculous pulmonary suppuration.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS COMPLEMENTING THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH, Secretary

CEVITAMIC ACID—Crystalline vitamin C, *lactone* $\text{CH}_2\text{OH}(\text{CHOH})\text{OCH}(\text{COH})\text{COHCO}$ (introduced as ascorbic

acid)—Cevitamic acid may be prepared from adrenal glands, citrus fruits, cabbage, paprika and other plant materials. It may also be prepared synthetically. It oxidizes on exposure to air and light and should be preserved in an oxygen-free atmosphere protected from light.

Actions and Uses—Cevitamic acid is indicated for prophylaxis and treatment of scurvy. Its use in caries, and in other conditions in which a deficiency of vitamin C may be a contributing factor, is not established.

Dosage—As a protective dose in infants, 0.01 Gm ($\frac{1}{8}$ grain), corresponding to from 15 to 30 cc. of fresh orange juice, the dosage for use in treatment has not been established.

Cevitamic acid occurs as white or yellowish white odorless monoclinic crystals often tabular—a few showing simple twinning. The optical properties are as follows: biaxial negative weakly pleochroic birefringence—strong (0.239) optic angle (2E) about 5 degrees extinction generally parallel but in some sections inclined about 12 degrees indexes of refraction $n = 1.466 \pm 0.002$ $n_g = 1.680 \pm 0.002$ $n_r = 1.705 \pm 0.002$. It is freely soluble in water, soluble in alcohol and insoluble in chloroform and ether. It melts between 189 and 192°C.

The rotation $[\alpha]_D^{25}$ of cevitamic acid determined in a solution containing the equivalent of 10 Gm in 100 cc. of the solution falls between +20.5 and +21.5.

To 1 cc. of a 2 per cent aqueous solution of cevitamic acid add 2 drops of sodium nitroprusside solution and make alkaline with tenth normal sodium hydroxide solution; a fine color is produced that changes to green and then to red. Add 2 cc. of 2 per cent aqueous solution of cevitamic acid to 5 cc. of Fehling's solution; the Fehling's solution is slowly reduced in the cold.

Transfer about 0.1 Gm. of cevitic acid, accurately weighed to a beaker containing 100 cc. of cooled distilled water that has just previously been boiled, and 25 cc. of diluted sulphuric acid titrate with tenth normal iodine solution using starch as an indicator (1 cc. of tenth normal iodine solution corresponds to 0.0088 Gm. of cevitic acid) the iodine used corresponds to not less than 98 per cent cevitic acid.

Transfer about 0.12 Gm. of cevitic acid accurately weighed to a beaker add 20 cc. of water and titrate with tenth normal sodium hydroxide using phenolphthalein as an indicator the alkali used is equivalent to not less than 99.5 per cent nor more than 100.5 per cent cevitic acid.

Transfer about 0.1 Gm. of cevitic acid accurately weighed to a wide-mouthed glass stoppered weighing bottle dry in a vacuum over phosphorus pentoxide for eighteen hours the loss is not greater than 0.3 per cent.

Transfer about 0.1 Gm. of cevitic acid to a platinum dish ignite to constant weight the ash is negligible.

Cebione-Merck—A brand of cevitic acid-N N R, obtained from vegetable sources

DIPHThERIA TOXOID, ALUM PRECIPITATED (REFINED) (See New and Nonofficial Remedies, 1934, p. 393)

Jensen Salsbery Laboratories, Inc., Kansas City, Mo

Diphtheria Toxoid Alum Precipitated (Refined)—Prepared from diphtheria toxin having an M L D value of 0.0025 cc. or less. The toxin is treated with formaldehyde until its toxicity is so reduced that five human doses will cause no local or general symptoms of diphtheria poisoning when injected subcutaneously into guinea pigs. The toxoid is precipitated by the addition of not more than 2 per cent of potassium aluminum sulphate, the precipitate is washed with physiologic solution of sodium chloride and resuspended in a volume of physiologic solution of sodium chloride equivalent to the volume of the original toxoid. Merbriolite, 1:10,000 is added as a preservative. The product is tested for antigenic potency according to the method prescribed by the National Institute of Health guinea pigs weighing 500 Gm. given one human dose must produce at the end of six weeks at least two units of diphtheria antitoxin in each cubic centimeter of blood.

Marketed in packages of 1 cc. (1 immunizing treatment) and in packages of ten 1 cc. vials (10 immunizing treatments)

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT

RAYMOND HERTWIG Secretary

EXPRESSION OF APPRECIATION TO CONSULTANTS WHO HAVE ASSISTED THE COMMITTEE

During the past year a number of authorities in their respective scientific fields were consulted on questions of moment before the Committee arising out of its regular business. In recognition of the helpful cooperation and valuable assistance given, the Committee has voted to express publicly its appreciation by publishing the names of those who in this manner and without remuneration have gladly contributed of their time, experience and knowledge to the benefit of the Committee in its public welfare and health work.

The Committee is officially thanking the following who have served as consultants

IRRADIATED VITAMIN D HOMOGENIZED PASTEURIZED MILK

Distributors—David Butterick Company, Arlington, 74, Mass. Urbana Pure Milk Company, Urbana, Ill.

Description—Bottled homogenized pasteurized vitamin D milk irradiated with ultraviolet rays

Preparation—The milk complies with legal requirements and is homogenized, and pasteurized by the standard holding method. For description of irradiation, see THE JOURNAL, Oct. 7, 1933, page 1155

Vitamins—Clinical investigation shows this milk to be a reliable antirachitic agent, if the proper amount is used. Contains 135 U S P X (Revised, 1934) vitamin D units per quart

Claims of Distributors—Irradiated antirachitic homogenized pasteurized milk having otherwise the flavor and food values of usual homogenized pasteurized milk. The cream does not separate

KISMET BISCUIT FLOUR

Manufacturer—Noblesville Milling Company, Noblesville, Ind.

Description—Biscuit mix requiring only addition of liquid for baking, contains flour (bleached), vegetable shortening, dry skim milk, dextrose, sodium acid pyrophosphate, salt and soda

Manufacture—The nonfat ingredients are thoroughly mixed, the shortening is cut in by means of special equipment. The mix of definite proportions of all ingredients is packed in paper sacks

Analysis (submitted by manufacturer) —	per cent
Moisture	8.8
Ash	2.8
Fat (ether extraction method)	9.1
Protein (N X 6.25)	9.8
Crude fiber	0.4
Carbohydrates other than crude fiber (by difference)	70.0

Calories—4.0 per gram 114 per ounce.

Claims of Manufacturer—Requires only the addition of liquid for the preparation of biscuit dough

(a) PALLAS BRAND CRYSTAL WHITE SYRUP

(b) NECTAR BRAND GOLDEN SYRUP

Distributor—Ridenour-Baker Grocery Company, Kansas City, Mo.

Packer—Bliss Syrup and Preserving Co., Kansas City, Mo.

Description—(a) A table syrup, corn syrup sweetened with sucrose syrup and flavored with vanilla.

(b) A table syrup, corn syrup flavored with refiners' syrup

Manufacture—(a) The same as Bliss Pancake Crystal White Brand Syrup (THE JOURNAL, Nov. 18, 1933, p. 1635)

(b) The same as Bliss Pancake Brand Golden Syrup (THE JOURNAL, Oct. 28, 1933, p. 1393)

Claims of Manufacturer—Recommended for use as an easily digestible and readily assimilable carbohydrate supplement to milk in infant feeding and as a syrup for cooking, baking and the table

SMITH'S HOLSUM BREAD SLICED

Manufacturer—Smith's Bakery, Inc. Mobile Ala.

Description—Sliced white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p. 817) prepared from unbleached flour, water, cane sugar, powdered skimmed milk, shortening salt, yeast a bleaching agent consisting of corn and soya bean flours and vinegar

SUDDEN AND UNEXPECTED DEATH

Sudden death may be violent, accidental, self inflicted, due to natural causes or unexpected. The suddenness with which death occurs may vary. The death may be unexpected by the victim's friends but anticipated by the person, family or physician. Violent death may be unexpected by the person but planned by others. The interpretation of the factors surrounding sudden death are therefore somewhat dependent on the point of view.

The medicolegal importance of sudden death is manifest. Medical testimony as to the exact cause of such death has done much to refute the now classic epigram "Witnesses may be divided into ordinary witnesses, liars, damned liars and expert witnesses." Thus Burke-Gaffney¹ cites several instances of sudden death apparently due to violence or poisons in which careful necropsy revealed a "natural cause" as the primary factor. Of equal legal and sociological interest are the cases in which the reverse situation has been found.

Numerous studies of sudden death resulting from "natural causes" have been made. A recent addition is that by Hamman,² who has reviewed the previous statistical observations. These he summarizes as follows: Ninety-one per cent of sudden deaths from natural causes are due to disease of the cardiovascular system, i. e., heart failure, hemorrhage and arterial embolism and thrombosis. Of the deaths from sudden heart failure, 65 per cent are due to diseases of the coronary arteries, 21 per cent occur with valvular heart disease, 10 per cent with myocardial disease, and 3 per cent with cardiac hypertrophy. Syphilis of the aorta is a conspicuously frequent cause of sudden death and occurs in about 20 per cent of all cases due to natural causes.

An accurate analysis of the mechanism involved is often fraught with great difficulties. Thus, as Hamman says, the circumstances attending sudden stopping of

the heart in the midst of apparent health have stirred endless curiosity. The gross anatomic alterations are usually extensive disease of heart muscle commonly due to obstruction of the blood flow in the coronary arteries. These changes must usually come about slowly. With the exception of abrupt occlusion of a large coronary artery there are no anatomic marks by which sudden cardiac death can be identified. In a small proportion of such cases, however, the mechanism has been demonstrated. There are, for example, a few recorded instances of patients dying while electrocardiographic records were being taken. The rapid regular rhythm immediately preceding death has been interpreted as ventricular flutter, the rapid irregular rate at the moment of death as evidence of ventricular fibrillation. It may be concluded that ventricular fibrillation occurs frequently in dying hearts and that it is the only mechanism so far discovered (except perhaps the abrupt onset of heart block or sino-auricular standstill) to account for sudden cardiac death. It is probably often the cause of temporary cessation of the heart beat, producing attacks of unconsciousness and convulsions.

The immediate results of fatal hemorrhage are due to loss of blood, the effects of pressure on a vital organ and damage to tissue from bleeding into its substance. The type of injury explains the less abrupt nature of "sudden death" occurring in this way. Thrombi formed in the systemic veins easily explain the method of pulmonary embolism. In man occlusion of the trunk or of both branches of the pulmonary artery is always followed by sudden death. Sometimes this follows when only one main branch is plugged. The latter does not occur in experimental animals, and some special explanation is therefore necessary to account for the difference in man. This factor may lie in the pre-existing condition of the heart. The mechanism of systemic arterial embolism is not always wholly clear. Paradoxical embolism, through a patent foramen ovale, may be preceded by pulmonary embolism, thereby increasing the right intra-auricular pressure and making the foramen ovale more patent.

About 9 per cent of the cases of sudden death are accounted for by other disorders. This group includes almost innumerable diseases which have occasionally been reported as a cause of sudden death. There is a recent tendency, backed by considerable evidence, to exclude so-called status thymicolymphaticus as non-existent as a clinical entity. Physical allergy, especially to cold, is now thought to be of some importance and perhaps to explain some of the deaths by drowning.

Nothing is so dramatic as sudden death. In cases due to accident or suicide, the cause is usually promptly apparent. Before our modern knowledge of heart disease, the cause in most other cases was a matter of conjecture. Now coronary thrombosis is the first thought. In 198 cases of sudden death on which postmortem was done in Leeds, 104, which constituted over 53 per cent

of all the cases, or 65 per cent of all of those over 40 years of age, were found to be due to diseases of the coronary arteries. In the prevention of sudden death, it must be remembered that irritation by any of a number of different causes may be secondarily responsible.

THE KUPFFER CELLS OF THE LIVER

Much has been published recently about the reticulo-endothelial system, which comprises large phagocytic cells present on the walls of the small blood vessels of many and perhaps all parenchymatous organs. Typical is the Kupffer cell in the vascular channels of the liver. The name refers to the Munich anatomist who first described these cells about 100 years ago. Not only are they intensely phagocytic, ridding the blood of all manner of harmful particles, especially bacteria, but also they are considered by many authorities to have other physiologic powers, notably the ability to form antibodies of various kinds in the development of resistance, and to be the site of normal blood destruction.

The existence and importance of this system of cells, though almost generally accepted, have depended on rather indirect observations. It has been impossible to observe them apart from the neighboring and associated cells, which are present in overwhelming numbers especially in the spleen and liver. That observation *in vitro* is an important source of information is shown by the work on muscle, for example, which has been extensively studied because it can be observed in an isolated state. In other words, what was needed for further investigation of this reticulo-endothelial system was the isolation of the cells in pure culture. This has now been possible by means of an ingenious procedure recently described by Rous and Beard,¹ working at the Rockefeller Institute in New York.

The experiment starts with the repeated intravenous administration into the experimental animal of colloidal iron (gamma ferric oxide), which has strong magnetic properties. The particles are taken up by the cells of the reticulo-endothelial system, including the Kupffer cells of the liver. The liver is then perfused under pressure, so that the cells become detached and are carried along with many other cells. The wash fluid, rich in many kinds of cells, is then passed over the pole of a large electromagnet, which attracts only the cells containing iron. In this way all other cells are carried away and a more or less pure culture of Kupffer cells is obtained. Cultivation of the cells was carried out under appropriate conditions, and for at least ten days they lived and multiplied. Some of their functions were studied and many interesting observations were made.

The Kupffer cell as seen in pure culture is tremendous in size, varying between 40 and 100 microns in diameter, thus bringing it within the limits of visibility

with the naked eye. It contains a single nucleus and is surrounded by an immense circular membrane. The stickiness of the cell is remarkable, any particle with which it comes in contact adheres tenaciously to its surface. Indeed, the cells grow and multiplication depends on their attachment to some anchoring structure. The New York experimenters found that lens paper provided them with an excellent framework for growth. Without such a support they withered and died. Although similar in character to the tissue phagocyte (macrophage) the Kupffer cell is much more sensitive to injury than any other form of white cell. With the effectiveness of the method demonstrated, it should be relatively simple to extend observations of this remarkable type of cell to include studies of its function in the vast and important field of resistance and immunity.

SURGICAL RELIEF OF PAIN

Search for relief from pain leads more people to seek medical help than any other symptom. Fortunately in the majority of instances the cause of this pain can be determined and removed or treated with subsequent relief. There are, however, types of pain so severe or so constant and insusceptible to causal relief that medical aid is limited to supplying drugs or to surgery. Pain of this character has recently been discussed by Learmonth.¹

The pathways of the nerve fibers that mediate somatic pain sensibility are well known. The same anatomic clarity does not exist for visceral pain sensation. The fibers from the viscera probably travel by way of the splanchnic systems to the long paravertebral sympathetic chains and from there reach the parent spinal nerves along the rami communicantes of the sympathetic system. They finally enter the spinal cord along its posterior nerve roots. Some experimental and clinical evidence indicates that the fibers do not all pass toward the brain in the same tracts as do sensations of somatic pain but probably ascend by a series of relays of short fibers, the course of which is nearer the gray matter of the cord than that of the somatic pain tract. An exact understanding of these anatomic and physiologic factors is a necessary preliminary to surgical attempts for the relief of intractable pain.

Before any operation is undertaken that has for its primary object the denervation of a painful part, according to Learmonth, it must be proved that direct attack on the lesion is impossible. Decision of this question may be necessary under any one of three sets of circumstances. 1 When the site of the lesion and the site of the pain are the same. 2 When the painful area is more extensive than the local lesion, as when a rectal carcinoma invades the nerves of the sacral plexus. 3 When the pain is a "referred" pain and the real lesion distant.

¹ Rous, Peyton and Beard, J. W. Selection with Magnet and Cultivation of Reticulo-Endothelial Cells (Kupffer-Cells). *J. Exper. Med.* 59: 57, (May) 1934.

¹ Learmonth, J. R. The Surgeon and Pain. *Brit. M. J.* 1: 47 (Jan. 12) 1935.

A plan of operation for the relief of pain must consider the different anatomic arrangements of pain fibers according to the somatic or visceral origin of the pain. Somatic pain fibers from the periphery are first concentrated in nerve trunks and may then pass through a plexus, spread out over posterior roots and finally be concentrated in the anterolateral tract. This tract is the most logical point of attack for the surgeon, for by dividing it properly maximal analgesia with minimal effect on other forms of neural conduction is obtained. Visceral pain fibers are concentrated in a strand or strands of one of the splanchnic nerves. They spread out again over the "roots" of the strand and possibly still further in the sympathetic paravertebral chains. There may then be a choice of many posterior roots over which to enter the cord. In the cord itself the fibers may pass by way either of the anterolateral tract or of the ground bundles close to the gray matter. Hence the most logical point to attack visceral pain fibers is the particular splanchnic strand in which they are first concentrated.

Learmonth discusses the possible operative procedures for the relief of somatic pain by attacking the peripheral nerves, the cranial nerves, the posterior roots and the anterolateral tract. Of these, with notable exceptions, division of the anterolateral tract appears to be the most promising. Indications for its application may be grouped into (1) pain due to the presence of an irremovable tumor that is pressing on or infiltrating contiguous nerves, (2) pain due to pressure on nerves by bony outgrowths, e. g., spondylitis, (3) pain due to intractable neuritis, e. g., diabetes and (4) pain in amputation stumps of the lower extremity. The operation (called chordotomy) may be performed for pain originating as high as the fifth thoracic segment and in rare instances has been used as high as the eighth cervical segment.

Many operations have been devised for the relief of purely visceral pain. Learmonth discusses only two of these. In angina pectoris it has been found possible to block afferent cardiac fibers outside the spinal canal by injecting alcohol into and around the upper five thoracic ganglions of the sympathetic chain on the left side. The procedure is not serious and many good results have followed its application. In pelvic visceral pain it must be remembered that the first "zone of concentration" of sympathetic fibers from the pelvic viscera is open to attack as the presacral nerve in front of the fifth lumbar vertebra. Presacral neurectomy is followed by little disturbance of function, and the only really undesirable sequel is sterility though not impotence in the male. The operation has been employed with success in certain cases of intractable cystitis and in the palliative treatment of inoperable malignant disease of the bladder and some other pelvic disorders.

When critically reviewed, surgical intervention aimed solely at the relief of pain seems to offer good prospects in certain diseases for which other methods of treat-

ment have proved insufficient or in themselves harmful. The great danger of such methods lies in the temptation to afford relief without preliminary intense efforts to determine and treat the underlying cause. This temptation must be resisted.

Current Comment

EVIDENCE OF LATENT BRUCELLA INFECTION

The method of spread of undulant fever has been the subject of discussion for a number of years. Hardy¹ and Thomsen² maintain that direct contact with the tissues of animals harboring some form of *Brucella* is perhaps the most frequent source of undulant fever in man. Opportunity for detailed investigation of this problem is offered by the packing plants in which workers are exposed to possible sources of infection over long periods. In the survey by Heathman³ in Minnesota, agglutination and allergic responses as observed by a delayed type of skin reaction were used as indexes of the extent of *Brucella* infection. A wide discrepancy was encountered between these two criteria, the skin test showing a strikingly high percentage of positive reactions among the workers in the packing plants while agglutination decreased with the length of service in the plant, that is, with the length of exposure to possible infection. Of the 1,096 workers observed, those in contact with the blood and the fresh tissues of beef showed the highest proportion of positive allergic responses (80.1 per cent positive as compared to 55 per cent in the group as a whole). Considering the entire group, the proportion of positive agglutinations was only 8.4 per cent. Hardy reported an equally high percentage among the general population of Iowa. In contrast, however, the percentage of positive allergic reactions was 54.7 among the workers in packing plants and 38.6 in a miscellaneous group. The percentage of positive skin reactions increased and remained high in the groups of workers that were most heavily exposed to the blood and the fresh tissue of beef. This may be the result of numerous and repeated exposures to small infecting doses or to bovine strains of *Brucella* of low virulence for man and causing only subclinical infections. That agglutination and skin reactions alone are not reliable criteria of the degree of infection with *Brucella* is evident from the high percentage of positive reactions in cases in which no clinical manifestations of the disease are observed or described. Agglutination was positive in virtually the same percentage of packing plant workers and of other groups apparently not exposed to infected material. The skin reaction, however, gave a greater percentage of positive results in the former group. Which of these tests may be considered a true index of the extent of exposure and resulting reaction can be determined only after further investigation.

PROCEEDINGS OF THE SPECIAL SESSION

MINUTES OF THE SPECIAL SESSION OF THE HOUSE OF DELEGATES OF THE AMERICAN MEDICAL ASSOCIATION, HELD AT CHICAGO, FEBRUARY 15 16, 1935

HOUSE OF DELEGATES

First Meeting—Friday Morning, February 15

The House of Delegates convened in the Red Lacquer Room of the Palmer House and was called to order at 10 a m by the Speaker, Dr F C Warnshuis

The Secretary read the call for the Special Session of the House of Delegates, as follows

Call for the Special Session

To the Members of the House of Delegates of the American Medical Association

In compliance with the official request of the Board of Trustees that the House of Delegates be convened in Special Session I, as Speaker, under authority of chapter III, section 2, of the By Laws, hereby officially call the House of Delegates of the American Medical Association to convene in Special Session in the city of Chicago, State of Illinois, at 10 a m, Central Standard Time, on the fifteenth day of February, 1935

The business to be transacted at this Special Session shall be limited to the consideration of the social and economic policies of the Association as related to pending and proposed legislation, to sickness insurance and to other matters which may be submitted by the Board of Trustees

The House shall remain in session, recessing from day to day, until its deliberations are concluded

Signed and Issued in San Francisco, California, January 21, 1935

FREDERICK C WARNSHUIS, M D

Speaker, House of Delegates, American Medical Association

Dr J D Brook Chairman of the Reference Committee on Credentials, stated that eighty-four delegates had filed proper credentials, and, on recommendation of Dr Brook, the House seated these delegates who then constituted the roll of the House

On motion of Dr Brook, seconded by Dr Arthur J Bedell, New York, and carried, alternate delegates were seated in accordance with the list presented by the Chairman

EXECUTIVE SESSION

Dr H B Everett, Tennessee, moved that the House resolve itself into executive session The motion was seconded by Dr A T McCormack, Kentucky, and carried

On motion of Dr A T McCormack, Kentucky, seconded by Dr A C Morgan, Pennsylvania, and carried, the presidents, presidents-elect and secretaries of state associations, the chairmen of committees on medical economics vouched for by their state secretaries, the officers of the American Medical Association, and the representatives of the Surgeon Generals of the Army, the Navy and the Public Health Service vouched for by them, were permitted to remain in the House.

On motions regularly made, seconded and carried, there were also admitted to the executive session representatives of the American Academy of Ophthalmology and Otolaryngology the executive secretary of the Wayne County Medical Society the deans of the class A medical schools the president president-elect and secretary of the Chicago Medical Society, the members of the Committee on Economics of the American Dental Association, and the president and executive secretary of the Medical Society of Milwaukee County

The Speaker appointed as Sergeants-at-Arms Dr R W Fouts, Nebraska, and Dr Morris Fishbein, Editor of THE JOURNAL

Statement by the Board of Trustees

Dr J H J Upham, Chairman, read an official statement from the Board of Trustees, as follows

The Board of Trustees requested that this special session of the House of Delegates be called for "the consideration of the social and economic policies of the Association as related to pending and proposed legislation, to sickness insurance and to other matters which may be submitted by the Board of Trustees"

In offering this subject for the consideration of the House of Delegates, the Board of Trustees feels that the members of the House should be properly oriented as to the manner by which we of the medical profession came into the present situation

The Board of Trustees deemed the present situation of such vital importance as to require that opportunity again be given for an expression through its official representatives of the well considered views of the organized medical profession of the United States on these subjects

SICKNESS INSURANCE

Sickness insurance is not unique as a subject for discussion in the House of Delegates In 1916 the American Medical Association developed a Committee on Industrial Insurance to study the whole question of social insurance for presentation to the House of Delegates At the same time the House of Delegates decided, through its committee to educate the American medical profession in the general principles of social insurance, to inform the profession concerning the subject, and to appear before legislative bodies in this country when advisable. In 1917 the Committee on Social Insurance presented a resolution to the House of Delegates authorizing a continuance of the study of social insurance and a molding of laws for the purpose so that the health of the community and the practice of medicine might be properly safeguarded At that time—in 1917—the principle was established that all such legislation should provide for freedom of choice of physician by the insured, for payment of the physician in proportion to the amount of work done, for separation of the functions of medical official supervision from the function of daily care of the sick, and for adequate representation of the medical profession on the appropriate administrative bodies

The committee presented reports to the House of Delegates at the sessions in 1916, 1917 and 1919, and the House of Delegates each year approved the report and directed the committee to continue its work In 1920 however, after a consideration of these reports, the American Medical Association, through its House of Delegates declared its opposition to the institution of any scheme embodying a system of compulsory contributory insurance against illness or any other scheme which provides for medical service to be rendered contributors or their dependents provided controlled or regulated by any state or federal government In 1922 the House of Delegates again declared its opposition to all forms of state medicine because of the ultimate harm that would come thereby to the public weal through such forms of medical practice And it defined state medicine as any form of medical treatment, provided, conducted, controlled or subsidized by the federal or any state government, excepting such service as is provided by the Army, Navy or Public Health Service and that which is necessitated by the control of communicable disease the treatment of mental disease or of the

indigent sick. This resolution was finally made to except also such other services as may be approved administered or conducted by local county medical societies and not disapproved by the state medical society of which it is a component part.

CHANGES IN THE NATURE OF THE PRACTICE OF MEDICINE

Since 1923 the medical profession of the United States has been increasingly aware of various plans for changing the nature of medical practice attempted in different communities under local auspices, in many instances with the approval of the county and state medical society directly concerned. In 1925, recognizing the influences at work leading toward a change in the nature of the practice of medicine, a Commission on Medical Education was developed which included representatives of the organized medical, dental, nursing and hospital professions, distinguished educators and leaders of public thought. This commission undertook a complete study of the medical scheme with a view to the development of recommendations for modification for the benefit of the public health, for the improvement of medical service and for the advancement of medical science.

It should be recognized also that schemes of sickness insurance under governmental auspices had been developed from time to time in foreign countries, beginning with the German one proposed by Bismarck in 1883 and followed by similar systems in other countries, culminating in the British system in 1911, proposed by Lloyd George. From time to time social workers, economists and physicians from the United States have gone abroad to study such systems and on their return have published in American periodicals the results of their studies. Moreover, *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* and other periodicals have regularly reflected these activities in the letters of foreign correspondents and in special articles published in *THE JOURNAL*, notably a series written by the Secretary of the British Medical Association especially for *THE JOURNAL*.

COMMITTEE ON THE COSTS OF MEDICAL CARE

In 1927, largely under the influence of three philanthropic foundations, the Twentieth Century Fund, the Milbank Fund and the Rosenwald Fund a committee of five was formed called the Committee on the Costs of Medical Care which was ultimately expanded to a committee of forty-eight. This committee also being planned to survey the entire medical setup in the United States and to bring out recommendations for providing the American people with what was called 'the best type of medical care at a price they could afford to pay.' Both the report of the Commission on Medical Education and of the Committee on the Costs of Medical Care were made available in 1932. These reports have had a considerable influence on the trend of American thought since the time of their publication relative to proposed changes in the nature of medical practice. In association with the development of this work, the American Medical Association established a Bureau of Medical Economics which was planned to compile, correlate and make available the facts in relationship to medical practice in the United States and also to undertake studies of new forms of medical practice developed from time to time in various places.

When the economic depression swept the United States toward the end of the presidency of Herbert Hoover, all plans for social change were held in abeyance while the nation gave the larger portion of its attention to the problems of recovery and relief. It was recognized that the satisfaction of such fundamental needs as employment, food, fuel and housing were primary and that questions of social change must be secondary until these needs had been satisfied.

Nevertheless, continuing experimentation with new plans of medical service arousing discord in the medical profession in many places were brought increasingly to the attention of the official bodies of the American Medical Association so that the House of Delegates of the Association at its meeting in Cleveland in June 1934 adopted ten fundamental principles to guide the medical profession in the control of experiments with new forms of medical practice.

At the same time the Judicial Council of the American Medical Association introduced certain amendments to the Principles of Medical Ethics recognizing the necessity for control of hospital practice, industrial practice, the practice of medicine

by commercial groups and similar forms. The question of compulsory sickness insurance did not even in June 1934 seem to loom largely on the medical horizon. Then on June 8, 1934, the President of the United States, just before departing on a vacation, announced his intention following his return to propose legislation for greater economic security for the people of the United States, and he indicated as primary objectives in such plans the question of unemployment and care of the aged.

THE COMMITTEE ON ECONOMIC SECURITY

In order to aid him in the development of these plans, a Committee on Economic Security was established including Frances Perkins, Secretary of Labor, Henry Morgenthau Jr., Secretary of the Treasury, Homer S. Cummings, Attorney General, Henry A. Wallace, Secretary of Agriculture, and Harry L. Hopkins, Director of Relief. This committee in turn set up a technical advisory staff with an executive director and in this technical advisory staff there were included some thirteen divisions of the problem of social security with such departments as unemployment, old age, maternal welfare, child welfare, care of the handicapped, dental care, hospital care, medical service and public health service. A technical director was installed for each of these departments and it was announced that the problem of medical service would be under a technical director.

Edgar Sydenstricker, an employee of the Milbank Fund who presented an individual minority report for the Committee on the Costs of Medical Care indicating his belief that its plans did not go far enough and that adequate provision for all of the people of food, fuel, clothing, housing and medical service must be the primary objectives of any social security plan, was made technical director for medical service.

Immediately on August 21, 1934, *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* made available to Hon. Frances Perkins an editorial in which it was pointed out that the medical profession must be adequately represented in any studies of the need for sickness insurance. To this Secretary Perkins replied with assurance that 'the advice of the medical profession will be obtained on all matters affecting it.' 'Moreover,' she said, 'it is our intention to obtain that advice through the appointment of a group of outstanding physicians and surgeons who will be available for consultations from time to time as the study develops.'

THE MEDICAL ADVISORY BOARD

These communications were referred to the Board of Trustees of the American Medical Association, which officially offered to Secretary Perkins as representatives of an organization of approximately 100,000 physicians, all the observations and the results of investigations made by the Bureau of Medical Economics of the American Medical Association as well as information and advice of all the officials and of the headquarters personnel together with any facilities of the Association. A similar communication was sent by the Secretary and General Manager to Mr. Edwin E. Witte, Executive Director of the Committee on Economic Security. In the meantime, efforts were made to determine the names of those who were to serve on the Medical Advisory Board. These names were held by the officials of the government in the greatest secrecy so that it was impossible to determine until just before the Medical Advisory Board's first meeting the names of those who had been asked to serve.

When the Medical Advisory Board met, the technical advisory staff for medical service was supplemented by the names of Dr. R. G. Leland and Mr. A. M. Simons of the Bureau of Medical Economics of the American Medical Association. Isidore Falk, a worker in the Milbank Fund, Michael M. Davis of the Rosenwald Fund and Nathan Sinai, who had conducted various investigations for the Michigan State Medical Society and who had drawn up an insurance plan for that society which, however, the society finally failed to adopt, had been previously added to the technical staff.

The Medical Advisory Board was told at the time of this meeting that the technical studies would be completed and that it would have opportunity later to offer its advice relative to certain plans which would be drawn up by the technical advisory staff. In the meantime the members of the Committee on Eco

conomic Security had been provided by the headquarters office of the American Medical Association with a statement on compulsory sickness insurance prepared by the Bureau of Medical Economics of the American Medical Association

When the Congress of the United States convened shortly after the beginning of 1935, the President of the United States in his message delivered January 4 indicated his plans for social security. Thus he said

Closely related to the broad problem of livelihood is that of security against the major hazards of life. Here also a comprehensive survey of what has been attempted or accomplished in many nations and in many states proves to me that the time has come for action by the national government. I shall send to you, in a few days definite recommendations based on these studies. These recommendations will cover the broad subjects of unemployment insurance and old age insurance of benefits for children for mothers for the handicapped for maternity care and for other aspects of dependency and illness where a beginning can be made.

Interesting was the manner in which the President passed immediately from unemployment insurance and old age insurance to the question of benefits for children, for mothers for the handicapped and for maternity care, leaving the question of sickness insurance to the phrase in which he said for other aspects of dependency and illness where a beginning can be made."

THE PRESIDENT'S MESSAGE

However, on January 17, 1935, the President sent to Congress a message relative to unemployment insurance old age pensions federal aid to dependent children, the support of existing mothers' pension systems, appropriations for services for the protection and care of homeless, neglected, dependent and crippled children, and finally additional aid by the federal government to state and local public health agencies and for the strengthening of the federal Public Health Service. Of sickness insurance the President said specifically

I am not at this time recommending the adoption of so-called health insurance although groups representing the medical profession are cooperating with the federal government in the further study of the subject and definite progress is being made

Coincident with the message to Congress by the President came a message from the Committee on Economic Security to the President and the report that it submitted to the President. The committee indicated again in its report the difficulties inherent in a sickness insurance program but seemed to forecast quite definitely its plans in relationship to this problem. Thus it said

As a first measure for meeting the very serious problem of sickness in families with low income we recommend a nation wide preventive public health program. It should be largely financed by state and local governments and administered by state and local health departments the federal government to contribute financial and technical aid. The program contains (1) grants in aid to be allocated through state departments of health to local areas unable to finance public health programs from state and local resources (2) direct aid to states in the development of state health services and the training of personnel for state and local health work and (3) additional personnel in the United States Public Health Service to investigate health problems of interstate or national concern

The second major step we believe to be the application of the principles of insurance to this problem. We are not prepared at this time to make recommendations for a system of health insurance. We have enlisted the cooperation of advisory groups representing the medical and dental professions and hospital management in the development of a plan for health insurance which will be beneficial alike to the public and the professions concerned. We have asked these groups to complete their work by March 1 1935 and expect to make a further report on this subject at that time or shortly thereafter. Elsewhere in our report we state principles on which our study of health insurance is proceeding which indicate clearly that we contemplate no action that will not be quite as much in the interests of the members of the professions concerned as of the families with low incomes

PLANS FOR HEALTH INSURANCE

The committee proceeded somewhat further along in its report to a brief consideration of so called health insurance, which still more elaborately hints at what is contemplated. Apparently the technical advisory staff of the Committee on Economic Security has made studies of the compulsory sickness insurance plans already established abroad. It has considered the possibilities of voluntary insurance and rejected them as well as the possibility of ordinary commercial insurance. It has already, it seems, prepared the basic principles for a tentative plan of insurance believed adequate for the needs

of American citizens with small means and appropriate to existing conditions in the United States. These are said to have been submitted to the professional advisory groups organized for the purpose. The advisory groups requested an extension of time and the extension was granted until March 1. The statement was made that 'arrangements have been effected for close cooperative study between the committee's technical staff and the technical experts of the American Medical Association'. In its report submitted to the President, the Committee on Economic Security offered the following information to the professions and to the public as to the main lines along which its studies are proceeding

1 The fundamental goals of health insurance are (a) the provision of adequate health and medical services to the insured population and their families (b) the development of a system whereby people are enabled to budget the costs of wage loss and of medical costs (c) the assurance of reasonably adequate remuneration to medical practitioners and institutions (d) the development under professional auspices of new incentives for improvement in the quality of medical services

2 In the administration of the services the medical professions should be accorded responsibility for the control of professional personnel and procedures and for the maintenance and improvement of the quality of service. Practitioners should have broad freedom to engage in insurance practice to accept or reject patients and to choose the procedure of remuneration for their services. Insured persons should have freedom to choose their physicians and institutions and the insurance plan shall recognize the continuance of the private practice of medicine and of the allied professions

3 Health insurance should exclude commercial or any other intermediary agents between the insured population and the professional agencies which serve them

4 The insurance benefits must be considered in two broad classes (a) cash payments in partial replacement of wage loss due to sickness and for maternity cases, and (b) health and medical services

5 The administration of cash payments should be designed along the same general lines as for unemployment insurance and so far as may be practical should be linked with the administration of unemployment benefits

6 The administration of health and medical services should be designed on a state wide basis under a federal law of a permissive character. The administrative provisions should be adapted to agricultural and sparsely settled areas as well as to industrial sections through the use of alternative procedures in raising the funds and furnishing the services

7 The costs of cash payments to serve in partial replacement of wage loss are estimated as from 1 to 1.5 per cent of pay roll

8 The costs of health and medical services, under health insurance for the employed population with family earnings up to \$3,000 a year is not primarily a problem of finding new funds but of budgeting present expenditures so that each family or worker carries an average risk rather than an uncertain risk. The population to be covered is accustomed to expend on the average about 4.5 per cent of its income for medical care

9 Existing health and medical services provided by public funds for certain diseases or for entire populations should be correlated with the services required under the contributory plan of health insurance

10 Health and medical services for persons without income now mainly provided by public funds could be absorbed into a contributory insurance system through the payment by relief or other public agencies of adjusted contributions for these classes

11 The rôle of the federal government is conceived to be principally (a) to establish minimum standards for health insurance practice and (b) to provide subsidies grants or other financial aids or incentives to states which undertake the development of health insurance systems which meet the federal standards

THE WAGNER-LEWIS BILL

Promptly on the submission of these messages and reports to the Congress of the United States, Senator Wagner of New York submitted in the Senate S 1130 which is known as the Wagner Bill for Social Insurance. It covers specifically old age assistance, aid to dependent children, earnings and employment excise taxes. It sets up a social insurance board composed of three persons appointed by the President, to be a part of the Department of Labor. This board is authorized, with the approval of the Secretary of Labor to appoint and fix compensation of all officers, attorneys and experts needed, without regard to civil service laws. Under this board will come the supervision of old age insurance unemployment compensation, accident compensation, health insurance and related subjects. Annuity certificates and taxes on payrolls of 3 per cent are provided as means of raising funds

Under the heading maternity and child welfare, this bill appropriates \$4,000,000 annually to enable the federal government to cooperate with the state agencies of health in extending and strengthening services for the health of mothers and children especially in rural areas and in areas suffering from

severe economic distress. This is to be administered by the Department of Labor. Each state is to get \$20,000 annually and \$1,000,000 is to be apportioned among states in proportion to the respective live birth rates. The Secretary of Labor may apportion \$800,000 among states that are unable to match the federal appropriation. Furthermore, the Secretary of Labor may use the remainder to make special demonstrations and conduct research in maternal care. To secure the federal funds, the states must submit their plans to the Children's Bureau and obtain approval.

For the care of crippled children the Wagner bill provides \$3,000,000 annually, to be handled in much the same way as the funds for maternal and child welfare are to be handled, also subject to approval of the Children's Bureau.

For child welfare services \$1,500,000 annually is allotted, also distributed and controlled along the same lines.

Finally, the Wagner bill appropriates \$10,000,000 annually to be administered by the Bureau of the Public Health Service. The bureau is to allot \$8,000,000 to the states in amounts determined on the basis of the need of each state for such assistance, to develop state health services, including the training of personnel for state and local health work and for the purpose of assisting counties or other political subdivisions of the states in maintaining public health programs. The sum of \$2,000,000 is to be made available annually to the Public Health Service for the further investigations of diseases and problems of sanitation and related matters.

In the meantime, various proponents of changes in the social order had been exceedingly active in developing plans for the promotion of sickness insurance schemes in the individual states. Most active was the group known as the American Association for Social Security, of which the executive secretary, Abraham Epstein, is most widely known. This group prepared a so-called social security bill for health insurance which proposed to establish a system of compulsory and voluntary state health insurance including practically all manual workers and their dependents under its compulsory provisions. It also provided that certain other persons might voluntarily avail themselves of the supposed benefits of the act, so that it would include eventually 95 per cent of the entire population of the United States. This bill was immediately promoted in all the individual states, and it is understood that it is to be offered in the individual state legislatures from time to time as they convene throughout the country.

ACTIVITIES OF THE HEADQUARTERS OFFICE

In order to meet this situation, the headquarters office of the American Medical Association has made available an editorial analysis of the Epstein bill and, through its Bureau of Legal Medicine and Legislation, its Bureau of Medical Economics and its Secretary's office, has been in direct communication with the individual state medical societies and state organizations, supplying them with information and a suitable analysis of this proposed legislation. Moreover, the Bureau of Medical Economics to meet the arguments offered by proponents of compulsory sickness insurance on a federal basis has developed a Catechism on Sickness Insurance, a series of articles on the sickness insurance schemes now operative in foreign countries, and a vast amount of data published in various places on this subject.

In the meantime, the Medical Advisory Board has had another session and it is no secret that the technical advisory staff proposes to assume complete responsibility for the recommendations incorporated in the final report to be made to the Committee on Economic Security, which in turn, will offer its suggestions to the President. It will then be for the President of the United States to determine what he proposes to present to Congress in a further message on this subject, and also whether or not any special legislation of federal character is to be introduced as an administration bill.

Members of the House of Delegates should of course, also be advised that at the time of this writing the Administration Relief Bill of \$4,800,000,000 to be disposed of by the President on his own responsibility is still undergoing hearings and that the Wagner bill has not yet been reported out of either House or Senate committees.

This is the status of the situation at this time. It remains for the House of Delegates to determine the policies of this organization for the guidance of its members and of its representatives.

QUESTIONS FOR THE HOUSE OF DELEGATES

Dr Upham also presented six questions suggested for discussion by the House of Delegates, as follows:

1 Shall or shall not the House of Delegates again declare its opposition to all forms of state medicine, including any form of medical treatment provided, conducted, controlled or subsidized by the federal or by any state government, excepting such service as is provided by the Army, Navy or Public Health Service and such as is necessitated by the control of communicable disease or for the treatment of mental disease or of the indigent sick, and excepting also all such other service as may be approved, administered or conducted by local county medical societies and not disapproved by the state medical societies of which they are component parts?

2 What is the attitude of the House of Delegates toward the eleven principles proposed by the Committee on Economic Security as fundamental to any system of sickness insurance to be established by the federal government?

3 Shall or shall not the House of Delegates of the American Medical Association reaffirm its opposition to the principle of federal subsidies to individual states in relationship to the provision of medical service?

4 Will the House of Delegates express its position relative to that provision of the Wagner bill which places the control of medical affairs in the Department of Labor under a non-medical special board?

5 What attitude shall the House of Delegates take relative to the proposed sickness insurance legislation in the individual states as represented by the Epstein bill of the American Association for Social Security?

6 How may the American Medical Association initiate plans for still further improving the quality of medical service and for obtaining better distribution of medical service for all the people?

Actions of the House of Delegates

Dr B F Bailey, Nebraska, moved that a Special Reference Committee be appointed to crystallize the expressions of the delegates and bring recommendations to the House for final action. The motion was seconded by Dr H B Everett, Tennessee, and carried.

Dr Charles E. Humiston, Illinois, presented a resolution urging on the President and Congress of the United States the creation of a new department under a secretary of health, which was referred to the Special Reference Committee.

Dr John W. Ames, Colorado, presented a resolution recommending that the dangers of the lack of free choice of physicians be brought to the attention of the President of the United States, which was referred to the Special Reference Committee.

At the request of Dr J C. Flippin, Virginia, the Secretary and the President explained the relation of the Committee on Economic Security, the Medical Advisory Board of that committee and the American Medical Association.

On motion of Dr Arthur J. Bedell, New York, seconded by Dr J D. Brook, Michigan, and carried the House authorized the appointment of a Press Release Committee consisting of Dr Holman Taylor, Texas; Dr Wells Teachnor Sr., Ohio; Dr J N. Baker, Alabama, and Dr Morris Fishbein, Editor of THE JOURNAL.

There was general discussion participated in by various delegates after which, on request of Dr J N. Baker, Alabama; Dr R G. Leland, director of the Bureau of Medical Economics, was asked to address the House. At Dr Leland's request, his appearance before the House was deferred until the afternoon session.

Special Reference Committee

The Speaker appointed the following members of the House of Delegates on the Special Reference Committee: Dr Harry H. Wilson, California, Chairman; Dr N B. Van Etten, New York; Dr E H. Cary, Texas; Dr W F. Braasch, Minnesota; Dr Warren F. Draper, Virginia; Dr F S. Crockett, Indiana; and Dr E F. Cody, Massachusetts.

The meeting recessed at 12 50 to reconvene at 2 30 p m.

Friday Afternoon, February 15

The House of Delegates reconvened at 2 30 p m, with Dr F C Warnshuis, Speaker, in the chair

Dr R G Leland, director of the Bureau of Medical Economics addressed the House, after which Dr William C Woodward, director of the Bureau of Legal Medicine and Legislation, on request, made a statement regarding his views of the situation

There ensued general discussion by the members of the House, during which Dr John F Hagerty, New Jersey, suggested that the proposals presented by the Board of Trustees at the morning session be restated and that the Board present its reaction to these proposals, and the suggestion was duly seconded There ensued further discussion, after which the Speaker presented his understanding of Dr Hagerty's suggestion, namely, that the House of Delegates consider the six points presented by the Board of Trustees during the discussion of which each delegate, as well as each member of the Board of Trustees, might give suggestions Dr Hagerty's suggestion was then adopted, and the six questions were restated and discussed seriatim by various members of the House

The Secretary read a telegram from Dr W G Ricker Vermont, who was unavoidably absent from the meeting This telegram, together with other similar telegrams, was referred to the Special Reference Committee

The House referred to the Special Reference Committee resolutions introduced by Dr R B Anderson, Texas requesting the House of Delegates to reaffirm its position in opposition to sickness insurance Other resolutions on the subject of sickness insurance, presented by Dr H C Macatee, District of Columbia, Dr Charles H Goodrich, New York, and Dr Walter E Vest, West Virginia, were also referred to the Special Reference Committee

A motion of Dr Isaac A Abt, Section on Pediatrics seconded by Dr J N Baker, Alabama, that a committee of nine be appointed to study all phases of this subject and report back to the House at the Atlantic City Session was referred to the Special Reference Committee

The House recessed at 5 25 p m, to reconvene at 10 a m, Saturday, February 16

Second Meeting—Saturday Morning, February 16

The House of Delegates was called to order at 10 a m Saturday, February 16, by the Speaker, Dr F C Warnshuis

Dr J D Brook, Chairman, presented the report of the Reference Committee on Credentials, offering credentials of additional alternate delegates, who were then seated by the House Dr Brook stated that there were 162 delegates registered

The action of the Secretary, in referring to the Special Reference Committee recommendations from the New Jersey delegates received at adjournment on Friday, was approved

The Secretary presented a communication from physicians in Boston requesting the House of Delegates to consider fully the Lundeen bill, H R 2827, and the workers health insurance bill

Resolutions urging the American Medical Association to sponsor and support actively legislation by Congress to remove the immigrant physician from his present exemptions from the quota under the 1917 immigration law, and a resolution in which the Section on Radiology endorsed such resolutions both introduced by Dr Albert Soiland, Section on Radiology, were adopted after discussion, on motions duly seconded and carried

Dr Hugh Cumming, Surgeon General of the United States Public Health Service, addressed the House

The Secretary then read the minutes of the Friday session of the House, which were adopted on motion of Dr George W Kosmak, New York, seconded by Dr J D Brook, Michigan, and carried

Dr E. A. Hines South Carolina moved that the minutes of the Special Session of the House be reported in the usual manner in THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION and the motion was seconded by Dr Arthur J Bedell, New York and carried

Dr Harry H Wilson, Chairman, read the report of the Special Reference Committee, which, after prolonged discussion, was referred back to the committee for redrafting

The House recessed at 12 noon to reconvene at 2 p m, and all those desiring to recommend revision of the report of the Special Reference Committee were invited to meet with the committee during the recess

Saturday Afternoon, February 16

The House reconvened at 2 p m, Saturday, February 16, with Dr F C Warnshuis Speaker, presiding

Dr Harry H Wilson, Chairman of the Special Reference Committee presented the following report, which, on motions duly seconded and carried, was unanimously adopted

REPORT OF THE SPECIAL REFERENCE COMMITTEE

Your reference committee, believing that regimentation of the medical profession and lay control of medical practice will be fatal to medical progress and inevitably lower the quality of medical service now available to the American people, condemns unreservedly all propaganda, legislation or political manipulation leading to these ends

Your reference committee has given careful consideration to the record by the Board of Trustees of the previous actions of this House of Delegates concerning sickness insurance and organized medical care and to the account of the measures taken by the Board of Trustees and the officials of the Association to present this point of view to the government and to the people

The American Medical Association, embracing in its membership some 100,000 of the physicians of the United States, is by far the largest medical organization in this country The House of Delegates would point out that the American Medical Association is the only medical organization open to all reputable physicians and established on truly democratic principles, and that this House of Delegates, as constituted, is the only body truly representative of the medical profession

The House of Delegates commends the Board of Trustees and the officers of the Association for their efforts in presenting correctly, maintaining and promoting the policies and principles, heretofore established by this body

The primary considerations of the physicians constituting the American Medical Association are the welfare of the people, the preservation of their health and their care in sickness the advancement of medical science, the improvement of medical care and the provision of adequate medical service to all the people These physicians are the only body in the United States qualified by experience and training to guide and suitably control plans for the provision of medical care The fact that the quality of medical service to the people of the United States today is better than that of any other country in the world is evidence of the extent to which the American medical profession has fulfilled its obligations

The House of Delegates of the American Medical Association reaffirms its opposition to all forms of compulsory sickness insurance whether administered by the federal government, the governments of the individual states or by any individual industry, community or similar body It reaffirms, also, its encouragement to local medical organizations to establish plans for the provision of adequate medical service for all of the people, adjusted to present economic conditions, by voluntary budgeting to meet the costs of illness

The medical profession has given of its utmost to the American people, not only in this but in every previous emergency It has never required compulsion but has always volunteered its services in anticipation of their need

The Committee on Economic Security, appointed by the President of the United States, presented in a preliminary report to Congress on January 17 eleven principles which that committee considered fundamental to a proposed plan of compulsory health insurance The House of Delegates is glad to recognize that some of the fundamental considerations for an adequate, reliable and safe medical service established by the medical profession through years of experience in medical practice are found by the committee to be essential to its own plans

However, so many inconsistencies and incompatibilities are apparent in the report of the President's Committee on Economic Security thus far presented that many more facts and details are necessary for a proper consideration.

The House of Delegates recognizes the necessity under conditions of emergency for federal aid in meeting basic needs of the indigent. It deprecates however, any provision whereby federal subsidies for medical services are administered and controlled by a lay bureau. While the desirability of adequate medical service for crippled children and for the preservation of child and maternal health is beyond question, the House of Delegates deplors and protests those sections of the Wagner bill which place in the Children's Bureau of the Department of Labor the responsibility for the administration of funds for these purposes.

The House of Delegates condemns as pernicious that section of the Wagner bill which creates a social insurance board without specification of the character of its personnel to administer functions essentially medical in character and demanding technical knowledge not available to those without medical training.

The so called Epstein bill proposed by the American Association for Social Security, now being promoted with propaganda in the individual states, is a vicious deceptive dangerous and demoralizing measure. An analysis of this proposed law has been published by the American Medical Association. It introduces such hazardous principles as multiple taxation inordinate costs extravagant administration and an inevitable trend toward social and financial bankruptcy.

The committee has studied this matter from a broad standpoint considering many plans submitted by the Bureau of Medical Economics as well as those conveyed in resolutions from the floor of the House of Delegates. It reiterates the fact that there is no model plan which is a cure-all for the social ills any more than there is a panacea for the physical ills that affect mankind. There are now more than 150 plans for medical service undergoing study and trial in various communities in the United States. Your Bureau of Medical Economics has studied these plans and is now ready and willing to advise medical societies in the creation and operation of such plans. The plans developed by the Bureau of Medical Economics will serve the people of the community in the prevention of disease the maintenance of health and with curative care in illness. They must at the same time meet apparent economic factors and protect the public welfare by safeguarding to the medical profession the functions of control of medical standards and the continued advancement of medical educational requirements. They must not destroy that initiative which is vital to the highest type of medical service.

In the establishment of all such plans county medical societies must be guided by the ten fundamental principles adopted by this House of Delegates at the annual session in June 1934. The House of Delegates would again emphasize particularly the necessity for separate provision for hospital facilities and the physician's services. Payment for medical service whether by prepayment plans, instalment purchase or so called voluntary hospital insurance plans must hold as absolutely distinct, remuneration for hospital care on the one hand and the individual personal, scientific ministrations of the physician on the other.

Your reference committee suggests that the Board of Trustees request the Bureau of Medical Economics to study further the plans now existing and such as may develop, with special reference to the way in which they meet the needs of their communities, to the costs of operation to the quality of service rendered, to the effects of such service on the medical profession and to the applicability to rural, village urban and industrial population, and to develop for presentation at the meeting of the American Medical Association in June model skeleton plans adapted to the needs of populations of various types.

The gist of the resolution introduced by Dr Charles H Goodrich, New York, has been included in the preamble of the report of your reference committee.

The resolution introduced by Dr Walter E Vest West Virginia, relative to representation of the Association in Washington and the communication introduced by Dr G Milton

Linthicum, Maryland, relative to presentation of the views of the profession to the government, are referred to the Board of Trustees.

The resolution presented by Dr C. E. Humiston Illinois, for the appointment of a secretary of health in the cabinet is referred to the Bureau of Legal Medicine and Legislation and to the Board of Trustees.

A proposed program asking for the drafting of a model law embodies principles not yet approved by this House of Delegates and is therefore referred to the Bureau of Legal Medicine and Legislation and to the Board of Trustees.

The resolution introduced by Dr J W Ames, Colorado, protesting interference with the right of free choice of physician in the Federal Relief Administration is referred to the Bureau of Legal Medicine and Legislation.

Resolutions offered by Dr R. B. Anderson, Texas, and by Dr H. C. Macatee, District of Columbia, the motion of Dr I. A. Abt, Section on Pediatrics, and a group of recommendations emanating from the Interstate Medical Economics Conference are covered by sections of the report of your Special Reference Committee.

Harry H. Wilson, Chairman, California
Warren F. Draper, Virginia
E. F. Cody, Massachusetts
E. H. Cary, Texas
N. B. Van Etten, New York
F. S. Crockett, Indiana
W. F. Braasch, Minnesota

Dr Wilson then moved that comments on the principles of insurance that had been submitted by Dr H. H. Shoulders Tennessee, be referred by the House of Delegates to the Bureau of Medical Economics. The motion was seconded by Dr E. G. Wood Tennessee, and carried.

It was moved by Dr Burt R. Shurly, Section on Laryngology, Otology and Rhinology, seconded by Dr C. E. Kiely, Ohio, and carried, that the report of the Special Reference Committee be given the widest possible publicity. It was suggested by Dr Holman Taylor Texas, that a professional propagandist be employed to publicize the report and to meet the propaganda of the opposition. Dr Morris Fishbein, Editor of THE JOURNAL, stated that arrangements for publicity had already been made, such as broadcasts and publication in THE JOURNAL and in HYGIEIA.

Dr C. B. Reed Illinois, presented resolutions urging that all clinics child welfare groups of whatever nature, and other social or charitable organizations having to do with medical problems be regarded as a part and attribute of medical practice, and moved the adoption of these resolutions. The motion was seconded by Dr C. S. Skaggs Illinois, and carried.

Dr McLain Rogers, Oklahoma suggested that a committee be appointed to contact the President of the United States.

It was moved by Dr F. S. Crockett, Indiana that the House of Delegates instruct its members that immediately on returning home they should contact their state association officers to call meetings of their respective houses of delegates to consider and act on the report of the Special Reference Committee concerning sickness insurance just adopted by this House of Delegates and report their action to the Secretary of the American Medical Association. The motion was seconded by Dr Charles J. Whalen Illinois, and after discussion, was lost by a vote of 55 to 63.

The motion of Dr Frederic E. Sondern, New York, seconded by Dr A. R. McComas, Missouri was adopted, as amended by Dr E. H. Cary Texas, namely, "It is the sense of the members of this House of Delegates that they are willing immediately to take the leadership of calling together the doctors of the states of the respective delegates to help inform them and solidify professional opinion as expressed here."

The Secretary read the minutes of the Saturday morning session of the House which were adopted.

It was moved by Dr Arthur J. Bedell, New York, seconded by Dr H. B. Everett, Tennessee and carried that the House arise from executive session.

Dr Austin A. Hayden Secretary of the Board of Trustees Dr J. H. J. Upham Chairman of the Board of Trustees Dr

Walter L. Bierring, President, and Dr. James S. McLester, President Elect, addressed the House.

Dr. Albert Soiland, Section on Radiology, requested that a message of the proper sort be sent to Surgeon General P. S. Rossiter, expressing sorrow for the illness of, and hope of recovery for, Captain McDowell of the Medical Corps of the United States Navy, and the Speaker stated that such a message would be sent by the Secretary.

Dr. C. A. Dukes, California, extended greetings from Dr. George Reinle, Vice President of the American Medical Association, who was unable to attend the Special Session.

The Speaker declared the House adjourned, sine die, at 3:50 p. m.

Association News

ABSTRACT OF MINUTES OF MEETINGS OF BOARD OF TRUSTEES HELD IN CHICAGO, FEBRUARY 14 TO 17

The Board of Trustees met at the headquarters office of the Association on February 14 and at the Palmer House on the 15th, 16th and 17th and gave careful consideration to the affairs of the Association.

SICKNESS INSURANCE

At its meeting on Thursday the Board of Trustees prepared a statement to be presented to the House of Delegates the following day giving an outline of the subject of sickness insurance, also a number of questions which the Board felt should be answered by the House of Delegates.

ELECTIONS

The following appointments were made for the various councils, committees and editorial boards: Council on Pharmacy and Chemistry—Drs. Morris Fishbein, G. W. McCoy and E. M. Bailey to succeed themselves, Dr. Howard J. Brown to succeed Dr. Stanhope Bayne-Jones, Dr. E. M. Nelson to succeed Dr. G. H. Simmons, and Dr. G. H. Simmons honorary member for life. Committee on Foods—Drs. G. F. Powers and Morris Fishbein to succeed themselves. Council on Physical Therapy—Drs. W. E. Garrey, W. W. Coblentz and John S. Coulter to succeed themselves. *Archives of Internal Medicine*—Dr. J. H. Musser, *Archives of Neurology and Psychiatry*—Dr. Adolph Meyer, *Archives of Otolaryngology*—Dr. George M. Coates, *Archives of Ophthalmology*—Dr. William Zentmayer, *American Journal of Diseases of Children*—Dr. H. F. Helmholtz, *Archives of Pathology*—Dr. Alfred Stengel—all to succeed themselves. *Archives of Dermatology and Syphilology*—Dr. Harold N. Cole to succeed Dr. W. T. Corlett. *Archives of Surgery*—Dr. Alton Ochsner to succeed Dr. Hugh Cabot. Committee on Scientific Research—Dr. Martin H. Fischer to succeed himself.

PUBLICITY OF INCOME TAX RETURNS

The Board of Trustees disapproved of the giving of publicity to income tax returns, and the director of the Bureau of Legal Medicine and Legislation was instructed to appear at the hearing on this new requirement and to present the views of the Board of Trustees.

APPROPRIATIONS

Appropriations were made for conducting the work of the various councils, bureaus and committees in the headquarters office as well as for exhibits and for research work.

MEDICAL BROADCASTS

Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45 central standard time. The next three broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

- March 7 Headache.
- March 14 Physical Defects.
- March 21 Rickets.

National Broadcasting Company

The American Medical Association broadcasts under the title 'Your Health' on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

March 5 Surgery in Diabetes. Ieland S. McKinnick, M.D., who will speak from the National Broadcasting Company's studios in Boston, by special arrangement.

March 12 Food and Drug Law Revisions. Paul N. Leech, Ph.D.

March 19 White Collar Hazards. W. W. Bauer, M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bill Introduced—H. 88 proposes to create a board of naturopathic examiners and to regulate the practice of naturopathy. Applicants for licenses must be high school graduates or have an equivalent education and be graduates of a school or schools of drugless therapeutics, approved by the board, requiring residential studies of not less than four years of eight months each. The bill states that naturopathy, which includes all forms of physiotherapy, is hereby defined to be a system of treating the abnormalities of the human mind and body by the use of drugless and nonsurgical methods, and includes the use of physical, electrical, hygienic, and sanitary measures incident thereto.

ARKANSAS

Bill Passed—S. 141 has passed the senate, proposing to repeal the laws regulating the sale, distribution or possession of narcotics and to enact what apparently is the uniform narcotic drug act.

Eclectic Licentiate Must Register—Within sixty days after Feb. 7, 1935 every licentiate of the Arkansas eclectic medical examining board must register with the secretary of the board. Failure to do so automatically suspends his right to practice. Registration must be accompanied by a fee of \$2 if the licentiate is a resident of Arkansas and by a fee of \$4 if he is a nonresident.

Bills Introduced—S. 184 proposes to authorize cities and incorporated towns to impose occupational taxes on physicians practicing within their jurisdiction. S. 213, to supplement the state food and drug act, proposes to transfer the administration of that act to the state board of health. It is to be the specific duty of every prosecuting attorney to whom the state health officer or any health or food or drug officer or agent of any county shall present satisfactory evidence of any violation of the act to institute appropriate proceedings for the enforcement of the act. S. 267 proposes to require the homeopathic medical board, the eclectic medical board, the "State Medical Board of the Arkansas Medical Society," the board of osteopathic examiners, and the board of chiropractic examiners to file with the secretary of state a list of all persons who have been licensed within the past twenty years giving the date the licenses were issued, the last known postoffice address of the licentiates and information as to whether the several licenses were issued after examination, or by reciprocity or if granted on a diploma. The boards referred to are to file with the secretary of state such information with respect to all licenses to be issued in the future by them, within one week of the issuance of the licenses. H. 217, to supplement the pharmacy practice act, proposes (1) to define drugs as follows: "Drugs means any drug or compound listed in the United States Pharmacopoeia or the National Formulary, or both, which are [sic] used for the prevention, mitigation or cure of disease;" (2) to prohibit the retail sale and distribution of drugs, as defined, except by registered pharmacies by physicians and by persons in communities not accessible to a registered pharmacy licensed by the board of pharmacy to sell and distribute drugs "conforming to the standards set by the United States Pharmacopoeia, or the National Formulary, or both;" and (3) to permit a court on the application of the board of pharmacy to enjoin the operation of any store not complying with the pharmacy laws.

CALIFORNIA

Correction—Bill Introduced—S 155 proposes to amend the medical practice act so as to authorize the board of medical examiners to issue a physician's and surgeon's certificate to an applicant who, although failing to furnish documentary evidence satisfactory to the board that he has completed a resident course of instruction fulfilling the requirements of the act, presents a diploma issued to him by a medical school approved by the board, and in addition files satisfactory documentary evidence of having either completed the fourth year in an approved medical school in the United States or having served at least one year in residence in a hospital in the United States approved by the board for internship. The item in *THE JOURNAL*, February 9, page 480, indicating that this bill tended to lower educational requirements, was based on an erroneous construction of the language of the bill.

Bills Introduced—S 820, to amend the medical practice act, proposes (1) to require persons who are licentiates of the board of osteopathic examiners on or before the first day of January annually to pay to the secretary-treasurer of the osteopathic board an annual registration fee of \$5 and (2) to provide that, in lieu of the requirement that an applicant for a license by reciprocity must have been a resident of the state which issued the certificate used as the basis of application for one year subsequent to the issuance of such certificate, the board may accept evidence of two years of licensed practice in another state. A 1009 proposes to raise to \$20 the annual permit fee required of clinics and dispensaries. A 1046 proposes to make it lawful for any practitioner of the healing art to enter into contracts or agreements with any of his patients to furnish them professional services or hospitalization and to exempt such agreements from the provisions of the insurance law. A 1096 and A 1097 propose to provide for the establishment of systems of health service insurance. These bills however were introduced by title only and presumably the committee to which they were referred, Social Service and Welfare, is to draft the bills. A 1202, to amend the law requiring hospitals, pharmacies and physicians treating persons suffering from wounds inflicted by knives, guns or other deadly weapons, to report such facts to appropriate police officials, proposes to require such reports of 'every person who renders or assists in rendering any treatment aid or service to any such injured person'. Reports are to be required to be made immediately after first treating or caring for such persons. A 1552 proposes to require applicants for licenses to practice any form of the healing art, as a condition precedent to examination by their professional boards to pass an examination to be given by a state board of qualifying certificate examiners in at least five of the following subjects: anatomy, physiology, chemistry, physics, botany, zoology, biology, hygiene, bacteriology and English. The board of qualifying certificate examiners is to be appointed by the Regents of the University of California and is to consist of five members, one member selected from the faculty of the University of California, one from the faculty of Stanford University, one from the faculty of the University of Santa Clara, one from the faculty of the University of Southern California and one from the faculty of the California Institute of Technology. The members of this board are to be selected because of their knowledge of the fundamental sciences enumerated. No member of the board is to be actively engaged in the practice of the healing art. A 1690, to amend the workmen's compensation act proposes that when an injured workman suffers from any disease or other physical impairment which delays or prevents the cure or relief from the disability caused by an industrial injury the employer is to be liable only for the reasonable cost of such medical, surgical and hospital treatment including nursing, as would have been required to cure or relieve the injury if such illness or physical impairment had not existed. A 1918 to amend the workmen's compensation act, proposes that the records of any hospital with respect to services rendered to any injured workman shall be exhibited to the patient or to his representative. The injured workman or his representative is to be permitted to make copies of such records including, but not restricted to, photostatic copies. A 1925, to amend the law relating to the use and disposition of unclaimed dead bodies, proposes that such bodies may be used for the purpose of instruction and study in the promotion of chiropractic education. A 2158 proposes to make it unlawful for any hospital clinic, physician or other person or institution possessing records concerning the condition of health of any person made while said person was in the care of such person or institution to refuse to exhibit such records to an attorney at law, designated by the patient in writing and to allow copies of the records to be made.

COLORADO

Bill Introduced—S 228 proposes to make it the duty of any physician, nurse or midwife, assisting in or in charge at the birth of any infant, or having its care after birth, to treat its eyes with a prophylaxis approved by the state board of health. This treatment is to be given as soon as practicable after birth but always within one hour.

Bills Passed—H 138 has passed the house, proposing to repeal the laws regulating the sale, distribution or possession of narcotic drugs and to enact what appears to be the uniform narcotic drug act. H 557 has passed the house, proposing to prohibit the retail sale or distribution of barbitol or other hypnotic or somnifacient drugs except on the prescription of a duly licensed physician, dentist or veterinarian. The prohibited drugs are barbitol, malonylurea, sulphonethylmethane (trional), sulphoumethane (sulphonal), diethyl-sulphon diethylmethane (tetronal), paraldehyde, chloral or chloral hydrate.

CONNECTICUT

Dr Chambers Gives Ferris Lecture—Robert Chambers, Ph.D., research professor of biology, New York University, New York, presented the Harry Burr Ferris Lecture in Anatomy at Yale University School of Medicine, New Haven, January 11. His subject was 'Mechanics of Cell Division.' It was illustrated by micromotion pictures of dividing cells manipulated by a microdissection technic.

Cancer Conferences—A series of conferences on problems relating to cancer research was conducted, January 24-31, at Yale University School of Medicine, New Haven by Dr Ernest Laurence Kennaway, director of the Research Institute of the Cancer Hospital, London. The purpose was an interchange of ideas between investigators in related fields. They were made possible by the trustees of the Anna Fuller Memorial Fund established in 1931 by the bequest of the late Egbert C. Fuller of New Haven for the study of cancer.

Social Aspects of Medicine—Edward Sapir, Sc.D., professor and head of the department of anthropology, Yale University, New Haven, made an address on "Human Beings as Personalities," March 4, in the series of lectures on the backgrounds of medical practice, which opened at the university January 14. These lectures are under the auspices of the department of public health of the university and are designed to help medical students especially to gain a broader view of human society and the role of medicine in it. Dr Sapir's lecture, February 18, on "Human Beings as Defined by Culture," was also included in the series. The first three lectures were given by Dr Henry E. Sigerist, director, Institute of the History of Medicine, Johns Hopkins University, Baltimore.

Bills Introduced—S 389 and S 396 propose to require both parties to proposed marriages as a condition precedent to obtaining licenses to wed to present statements from licensed physicians that both parties have submitted to a Wassermann or Kahn or other similar standard laboratory blood test and that the result of such test has proved negative. H 241, to supplement the naturopathic practice act, proposes to authorize the board of naturopathic examiners to issue a license to any naturopath who was engaged in practice within the state prior to July 1, 1923, and who is a graduate of a legally chartered reputable school or college of naturopathy approved by the board. H 443 proposes to appropriate \$1,000 to the state department of health to be used for such treatment of indigent typhoid or paratyphoid fever germ carriers as may be necessary to relieve them of the carrier state. H 577 proposes that on the conviction of a woman for violating the law prohibiting prostitution and lewdness she shall be examined for venereal disease. If she is found infected she is to be placed under treatment and is to be detained until she is no longer a menace to the public health. H 633 proposes to amend the law requiring physicians and midwives in attendance at the birth of a child to instill a prophylactic solution in the eyes of the baby by requiring such prophylactic solutions to be approved by the state department of health. H 814 proposes that any person, committed to any penal or charitable institution by any court, who is afflicted with any venereal disease, be detained in such institution and treated until he may be discharged therefrom without danger to the public health. H 853, to amend the medical practice act, proposes that "the use of the roentgen or x-ray or of radium in any manner for the treatment of any person shall be deemed to constitute the practice of medicine and surgery." H 1162, to amend the naturopathic practice act, proposes to raise the annual registration fee required of licentiates to \$5. H 1163 to amend the workmen's compensation act, proposes to permit chiropractors to render the "medical" treatment which the employer is required to furnish an injured workman.

DISTRICT OF COLUMBIA

Medical Bills in Congress—S 1016 has been reported to the Senate, proposing to empower the health officer of the District of Columbia to authorize the disinterment and reinterment of bodies in cases in which death has been caused by certain contagious diseases (S Rept No 124)

GEORGIA

Bills Introduced—H 204 proposes to authorize the sterilization of certain socially inadequate inmates of state institutions. H 561 proposes, among other things to levy an annual occupational tax of \$15 on practitioners of medicine, osteopathy, chiropractic, chiropody, and dentistry. H 178 proposes to repeal the laws regulating the sale, distribution or possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

Bills Passed—S 82 has passed the senate proposing to create a board of physiotherapy examiners and to regulate the practice of physiotherapy. The practice of physiotherapy is defined as "the diagnosis and treatment of human ailments by the use of any natural force or agency, the basis of which is water, heat, sunlight, electricity or electrically produced energies, mechanical appliances, ultra-violet light, infra-red light, manipulations, corrective exercises, dietetics, massage, external applications and mineral baths." The bill proposes to prohibit anybody but a licensee of the board from practicing physiotherapy as above defined but exempts (a) persons authorized by law to practice medicine and surgery and (b) persons who at the time of the enactment of the bill are members of the Georgia State Association of Physical Therapy or who have been engaged in the practice of physiotherapy for one or more consecutive years prior to the enactment of the bill. Applicants for licenses must be graduates from high schools or have equivalent education, must have studied physiotherapy for two years in a school of physiotherapy, approved by the board, and must pass a satisfactory examination in histology, anatomy, physiology, chemistry, pathology, diagnosis and treatment, bacteriology, massage, therapeutics, clinical physiotherapy and such added subjects as shall subsequently be taught by accredited schools of physiotherapy. S 60 has passed the senate, proposing to repeal the laws regulating the sale, distribution or possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

ILLINOIS

Bills Introduced—H 319 proposes that no one shall be employed to teach in the common schools of the state who does not present a physician's certificate showing that the applicant is free from contagious, infectious or communicable diseases. H. 320, to amend the medical practice act, proposes to authorize the revocation of the license of any practitioner who knowingly issues "a false certificate to any person to aid such person to obtain an appointment as a teacher in the schools of the state and showing such person to be free from contagious, infectious and communicable diseases."

Chicago

Lectures in Ophthalmology—Dr Karl Lindner, professor of ophthalmology, University of Vienna, will give a series of lectures at Northwestern University School of Medicine, April 9-12. He will discuss retinal detachment, trachoma, pathology underlying fundus diseases, and bacteriology of the eye. There will be a charge of \$10 for the course. Reservations may be made with Dr Earle B. Fowler, 55 East Washington Street.

Faculty to Present Program—Members of the faculty of the University of Illinois College of Medicine will present the program before the Chicago Medical Society at its meeting March 6. Drs George B. Hassin and Eric Oldberg will discuss respectively, the clinicopathologic features and surgical treatment of spastic paraplegias, and Drs H. Douglas Singer and Abraham A. Low will consider "Psychotic Symptoms and Their Significance."

INDIANA

Bills Introduced—H 365 proposes to authorize the construction and maintenance of hospitals by cities of the fourth and fifth classes. Such hospitals are to be open to all persons on reasonable terms and are also to be open on reasonable terms to all physicians who desire to place patients therein. S 234 proposes to authorize the establishment of an additional state hospital for the treatment of tuberculosis.

IOWA

Tuberculosis Survey—Linn County has been selected for a tuberculosis survey, according to the bulletin of the county medical society to be made as a federal public health project. Its purposes are to determine the physical condition of persons who have been patients in a tuberculosis sanatorium, to examine tuberculosis contacts by means of diagnostic tuberculin and the x-rays, and to do mass tuberculin testing when feasible and desirable locally. State and local health agencies are cooperating in the project, which was to have begun early in February.

Lectures for the Public—The speakers' bureau of the Iowa State Medical Society sponsored a course of health lectures for lay audiences when it opened a series, January 16, in Grinnell. Dr Milford E. Barnes, Iowa City, was the speaker on infectious diseases and their control. Dr Thomas U. McManus, Waterloo, discussed the common cold, January 23. Dr Arthur Steindler, Iowa City, infantile paralysis, January 30 and Dr Douglas N. Gibson, Des Moines, February 6, accidents. Should the response to these lectures be favorable the bureau plans to present similar series in other communities.

KANSAS

Bills Introduced—H 357 proposes to authorize the state board of health to secure, prepare and distribute infantile paralysis serum to serum stations throughout the state. H 471 and S 411 propose to authorize Fort Hays Kansas State College to provide local and traveling clinics and adequate psychological facilities for unusual and abnormal children of school age. H 516 to amend the law relating to the qualification and personnel of the state board of health, proposes to authorize the governor to appoint as a member thereon a licensed dentist.

Bill Passed—H 257 has passed the house, proposing that, whenever in the opinion of the warden of the state penitentiary at Lansing asexualization will be beneficial to the physical, mental or moral condition of any recidivist confined therein or any inmate who is a sexual pervert or degenerate, or any convict serving a life term for premeditated murder, or any convict who escapes or attempts to escape from the penitentiary, it shall be the duty of the board of administration to institute proceedings looking toward the sexual sterilization of such persons.

MAINE

Bills Introduced—S 394, to amend the chiropractic practice act, proposes (1) to require an applicant for a license, in addition to the qualifications now required by law, to be a graduate of a legally chartered chiropractic college in good standing requiring personal attendance and conferring degrees on the completion of a course of four school years of not less than six months each, and of a total of 2,600 sixty minute school hours. (2) to provide that a license to practice chiropractic shall entitle the holder thereof to practice chiropractic in all its branches as taught and practiced by the recognized schools and colleges of chiropractic, but it shall not authorize the practice of obstetrics so far as the same relates to parturition or to administration of drugs or the performance of surgical operations with the use of instruments and (3) to define chiropractic as "the science of locating and correcting interference with nerve transmission and expression, without the use of drugs or surgery, by such methods as are taught in reputable chiropractic schools and colleges." H 1348, to amend the chiropractic practice act, proposes to eliminate those provisions of the act requiring applicants for licenses to pass examinations.

MASSACHUSETTS

Dr Cannon to Lecture in China—Dr Walter B. Cannon, George Higginson professor of physiology, Harvard Medical School, Boston, will serve as visiting professor of physiology at the Peiping Union Medical College from April 15 to June 1, Science reports. He plans to attend the International Physiological Congress in Leningrad and Moscow in August.

Dr Faxon Appointed Director of Massachusetts General Hospital—Dr Nathaniel Wales Faxon, since 1922 director of Strong Memorial Hospital, University of Rochester, Rochester, N. Y., has been appointed director of the Massachusetts General Hospital and the Massachusetts Eye and Ear Infirmary, Boston. Dr Faxon, who graduated from Harvard Medical School in 1905, was assistant director of the Massachusetts General Hospital from 1919 to 1922. He is 54 years old and a former president of the American Hospital Association. He will succeed Dr George H. Bigelow who has been missing since December 1934.

MICHIGAN

Faculty Farewell to Dr Novy—An embossed plaque was presented to Dr Frederick G Novy, retiring dean of the University of Michigan Medical School, Ann Arbor, at a special executive faculty meeting, February 7. The meeting also marked the induction into office of Dr Albert C Furstenberg as dean. The resolution inscribed on the plaque acknowledged Dr Novy's years of service to the university and noted the regret of his colleagues that he will no longer be associated with them.

Bills Introduced—H 212 proposes to exempt from the provisions of the state sales tax law proceeds from the retail sale of medicines. S 121, to amend the chiropractic practice act, proposes that all moneys received by the board of chiropractic examiners be paid promptly into the state treasury and be credited to the general fund of the state to be disbursed as otherwise appropriated by the legislature. Under the present law the board is required to pay monthly all moneys received to the state treasurer.

MINNESOTA

Bill Passed—H 7 has passed the house, proposing to make it unlawful for any person to raise marijuana or prepare or manufacture marijuana into any product usable for smoking purposes.

Jackson Lecture Postponed—Dr Logan Clendenning, professor of clinical medicine University of Kansas School of Medicine, will deliver the second Clarence Martin Jackson lecture of the University of Minnesota School of Medicine March 8 instead of February 20 as formerly announced. Dr Clendenning's lecture will be entitled "The Human Side of Medicine."

Society News—Speakers before the Hennepin County Medical Society at its February meetings included Drs Elmer L Seyringhaus Madison Wis, February 4 on "Diagnostic and Therapeutic Questions in the Menopause" February 6 Emil Goetsch, Brooklyn Phases of the Gout Problem with Particular Reference to Iodine Therapy. February 13 Aaron Friedell, Minneapolis Medical Cooperation with Independence or State Medicine—Which Shall It Be? and Chester A Stewart, Minneapolis Primary Tuberculosis Infection An Asset or a Liability. February 20 William B Roberts 'Relation of Vital Capacity and Allied Tests to Circulatory Capacity of Ambulant Cases' and Gilbert Seashore 'Duties Responsibilities and Powers of the Coroner's Office.' Dr William A O'Brien, St Paul conducted a pathologic conference February 27. Plans to employ a full time executive secretary have been approved by the executive committee of the society.

MISSOURI

Bill Passed—S 28 has passed the senate proposing to make it unlawful for any person to cultivate cure prepare, distribute in any manner or possess marijuana. Physicians dentists and osteopaths however are to be permitted to prescribe marijuana.

Bills Introduced—H 423 proposes to repeal the laws regulating the sale distribution or possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act. H 307 to amend the medical practice act proposes (1) that applicants for licenses in addition to the qualification now required by law be at least 21 years of age be citizens of the United States, have actually lived in the United States one year prior to the making of their applications be able to read and write in the English language and have received a diploma from some medical college in the United States prescribed [sic] by the board and/or recognized and approved by the American Medical College Association, (2) that the board of health shall have the exclusive right to determine the reputability of medical schools or at its discretion may accept a medical school recognized and approved by the American Medical College Association and (3) to raise from \$15 to \$25 the fee required of applicants.

MONTANA

Bill Introduced—H 360 to amend the medical practice act, proposes to forbid so-called "Chinese Doctors," "Chinese Herb Doctors," "Chinese Specialists" and "Chinese Herbalists" from selling, advertising prescribing, directing or recommending any herbs, roots, barks or berries or any compound, liquid or otherwise for the cure relief or palliation of any ailment or disease of either mind or body, without a license to practice medicine.

NEBRASKA

Society News—Drs Donald R Black and James G Montgomery, Kansas City, Mo., addressed the Omaha Douglas County Medical Society, Omaha, February 12, on "Modern Treatment of Diabetes" and "Surgery of the Spleen," respectively.

Bill Introduced—S 326 proposes to authorize the county board of commissioners or supervisors of any county to create a public health department to prevent the introduction and spread of contagious, infectious and malignant diseases in the county. Such county public health department, when created, is to assume the duties of the health departments in villages, towns and cities in counties of less than 40,000 population. In counties where there are cities of 40,000 or more inhabitants, the governing bodies may make arrangements with the county boards to consolidate their public health departments or to coordinate the public health work. Two or more contiguous counties are also authorized to make arrangements to consolidate their public health departments and to coordinate their public health work.

NEVADA

Society News—Dr Albert G Clark, Boulder City, addressed the Clark County Medical Society, January 8, on "Renal Tuberculosis."—A paper on "Blood Transfusion" was presented before the Washoe County Medical Society at its meeting, January 8, by Dr Lawrence Parsons, Reno.

Bill Introduced—S 57 proposes to require applicants for licenses to practice medicine, osteopathy, chiropractic, naturopathy or any other system of healing that may hereafter be legalized in the state, as a condition precedent to examination by their professional boards, to pass examinations to be given by an impartial board in human anatomy, human physiology, human pathology, chemistry and hygiene. The examining board is to be appointed by the Board of Regents of the University of Nevada from the faculties of the University of Nevada. No member is to be actually engaged in the practice of any method or system of healing or have any financial interest in or be a member of the faculty of any school of medicine and surgery, osteopathy, chiropractic or any other school of healing.

NEW HAMPSHIRE

Bills Passed—H 196 proposing to limit the administration of anesthetics to licensed physicians and dentists, passed the house but has been recalled by the house public health committee for redrafting. H 270 has passed the house, proposing to amend the chiropody practice act so as to define a chiropodist as 'one who examines, diagnoses or treats medically, mechanically, surgically, or by electrical and manipulating means, or by bandaging and strapping, the ailments of the human foot, not requiring the use of anesthetics other than local.'

NEW JERSEY

Bills Introduced—S 134 proposes to grant to physicians liens for their reasonable charges in treating persons injured by the negligence of others, on any judgments or settlements obtained by such injured persons by reason of their injuries. Such liens, however, are to be limited to an amount not over 25 per cent of the amount of said judgments or settlements. The existing law on the subject contains no such limitation. A 142 A 143 and A 144, to supplement the workmen's compensation act are companion bills, introduced at the same time and constitute a single operative arrangement for preventing controlling, and compensating for silicosis. A 151, to amend the laws regulating the practice of chiropody, proposes to create an independent board of chiropody examiners, to examine and license applicants for licenses to practice chiropody. Under the present law, the state board of medical examiners examines and licenses applicants. A 182, to amend the laws regulating the sale, distribution or possession of narcotic drugs, proposes to prohibit any person other than a dealer in surgical instruments, an apothecary, a physician, a dentist, a veterinarian a nurse or an intern from possessing a hypodermic needle or hypodermic syringe, or any other instrument adapted for the use of cocaine or narcotic drugs by subcutaneous injections, unless such possession is obtained by means of the prescription of a physician, dentist or veterinarian, issued within the preceding year. A 184, to amend the workmen's compensation act proposes to ameliorate the conditions under which workmen can receive compensation for hernias arising in the course of employment. The bill proposes that when there is traumatic hernia resulting directly from the application of force directly to the abdominal wall, either puncturing or tearing it, compensation will be allowed. All other cases will be compensable.

provided a preponderance of proof is offered that the hernia was caused by such sudden effort or severe strain that the descent of the hernia followed within twenty-four hours of the cause, that there was severe pain in the hernial region, that the workman was compelled to cease work within twenty-four hours, that the foregoing facts were of such severity that they were noted by the workman and communicated to his employer within forty-eight hours after the occurrence of the hernia, and that there was such physical distress that the attendance of a physician was required within forty-eight hours after the occurrence of the hernia. A 185 to amend the law providing liens for hospitals and physicians caring for persons injured through the negligence of others on rights of action, claims and demands accruing to the injured persons by reason of their injuries, proposes to make the lien applicable only to hospitals. A 238, to amend the provisions of the medical practice act relating to osteopathy, proposes to authorize such osteopaths to practice surgery as, after graduating from a four year course in a reputable osteopathic school including courses in the principles and practice of surgery, have served as interns for at least one year in a reputable hospital or postgraduate school or as full time assistants to licensed surgeons. The bill proposes to eliminate those provisions in the present law which specifically prohibit osteopaths from prescribing or administering medicine and also proposes to denominate the practice of osteopathy as the practice of osteopathic medicine which, the bill states, 'shall include the diagnosing, treating, operating or prescribing for any human disease, pain, injury, deformity, physical or mental condition'.

NEW MEXICO

Bill Introduced—S 41 proposes to amend the law prohibiting the planting, cultivating production or sale or other distribution of cannabis indica so as to prohibit also its possession except on the written prescription of a licensed physician.

Bill Passed—H 181 has passed the house, proposing to create a board of naturopathic examiners and to regulate the practice of naturopathy. Naturopaths who have had actual practice in the state for two years are to be licensed without examination. Other applicants must be graduates of chartered schools or colleges of naturopathy teaching resident courses of not less than 3 600 hours and which require a high school education or its equivalent as a condition to admittance. A license to practice naturopathy is to entitle the holder thereof to administer any and all natural and constructive treatment in human ailments which are calculated to relieve suffering and/or restore health without the internal use of medicines, drugs or iodines, and to issue birth health and death certificates.

NEW YORK

Practitioners' Clinics at Rochester—Strong Memorial Hospital, Rochester, began a series of clinics for registered physicians, January 17 which will be continued through November on the third Thursday of each month. Dr Charles L. Scudder, Boston, was guest clinician at the first meeting discussing 'The Bases of the Treatment of Fractures'. Later clinics will be conducted by members of the staff.

Health at Utica—Telegraphic reports to the U S Department of Commerce from eighty-six cities with a population of 37 million for the week ended February 16, indicate that the highest rate (24.2) appears for Utica and the rate for the group of cities as a whole, 12.6. The mortality rate for Utica and for the group of cities as a whole for the corresponding week of 1934 was 13.6. The annual rate for the group of cities for the seven weeks of 1935 was 13.1 as compared with 12.6 for the corresponding period of last year. Caution should be used in the interpretation of weekly figures, as they fluctuate widely. The fact that some cities are hospital centers for large areas outside the city limits or that they have a large Negro population may tend to increase the death rate.

Bills Introduced—S 957 to amend the education law proposes to authorize the establishment of colleges of natural therapy. The commissioner of education is to prescribe rules and regulations for the establishment and regulation of such colleges which are to be authorized to issue degrees to matriculated students who have completed a four year course of study. The bill states that "a doctor of natural therapy shall be deemed to be a person who has successfully taken a course of study prescribed by the regents of the University of the State of New York in a college recognized by it in 1. Hydrotherapy (mineral waters) 2. Balneology (mineral bathing) 3. Cibology (preparation of foods for the sick) 4. Dietology (dietetics and metabolism) 5. Hirudology (application of leeches) 6. Hygiene (sanitation sterilization antiseptic [sic] and aseptic work) 7. Clismology (lavage of

stomach, bladder and colonic irrigation) 8. Lavatology (the relaxation of muscles, tendons, joints) 9. Massage (kneading [sic], exercise, under water exercise) 10. Phlebotomy (application of cupping, plasters, salves) 11. Potology (drinks, teas in sickness) 12. Rotology (rotation of various parts of the body to relax and release) 13. Electrolysis (removal of hair by electricity) 14. Scalp treatment (to prevent hair falling and baldness) 15. Physiotherapy (the application of diathermy [sic], ultraviolet and other radiations under physicians orders)". The bill is not clear whether or not such a 'doctor' would be permitted, without the examination and licensure required by the medical practice act, to practice the tenets of this school of natural therapy. A 123 and A 166 propose that whenever it is relevant to the prosecution or defense of an action, the court may require any party to the action and the child of any such party to submit to blood tests to be made by duly qualified physicians under such restrictions and directions, as the court or judge deems proper. The results of the tests made by the physicians are to be admissible in evidence.

New York City

Diphtheria Immunization Record—The largest number of diphtheria immunizations in any year since 1929 185,586, was reported by Dr John L. Rice, health commissioner, for the year 1934. Of the number of children immunized 117,569 or 64 per cent were under 6 years old. In 1929, when the Diphtheria Prevention Commission began its intensive drive, 211,985 children were immunized. Since this commission ceased to function in 1931, the work has been carried on by the health department without outside funds. In 1932 there were 166,243 immunizations, in 1933 there were 161,611. Deaths in the three year period 1932-1934 fell to an average of 133 per year, contrasted with 750 when the demonstration was begun in 1929.

Personal—Dr Jacob J. Golub, director of the Hospital for Joint Diseases will be consultant to the building committee of the Rothschild-Hadassah-University Hospital in Jerusalem which is shortly to be built.—Roy Chapman Andrews, explorer and naturalist has been appointed director of the American Museum of Natural History to succeed George H. Sherwood who resigned. Mr Andrews has been connected with the museum for many years as the leader of field expeditions into Central and Far Eastern Asia.—Dr Adam Eberle, medical superintendent of Kings County Hospital, has been appointed acting general medical superintendent of all city hospitals.—Dr John F. Erdmann, for more than twenty years director of the department of surgery of the New York Post-Graduate Medical School and Hospital, was the guest of honor at the annual dinner of the faculty association January 26. A bust of Dr Erdmann was unveiled at the dinner and it was announced that a new amphitheater at the school is named for him.

NORTH CAROLINA

Bill Introduced—H 293, to amend the workmen's compensation act proposes to make some twenty-five occupational diseases compensable, included among which are anthrax, compressed air illness, chrome ulceration, silicosis, asbestosis, tenosynovitis, bursitis, miners' nystagmus, and poisoning from arsenic, brass, zinc, manganese, lead, mercury, phosphorus, carbon bisulphide, methanol, naphtha, halogenated hydrocarbons, benzol, nitro and amido derivatives of benzol, radium, carbon monoxide, sulphuric, hydrochloric and hydrofluoric acid.

NORTH DAKOTA

Bill Introduced—H 201 proposes a procedure whereby county commissioners may levy a tax of not exceeding 6 mills on every taxable dollar of real estate and personal property within the county to pay for medical, surgical and hospital care for all of the residents of the county. Residents apparently are to be permitted to choose any physician or hospital they desire and the county will pay for the services according to a stated schedule.

OHIO

Bills Introduced—S 95 proposes to authorize the asexualization of feeble-minded and epileptic inmates or patients of hospitals or other state or county institutions supported in whole or in part by public funds. S 97 proposes to amend those provisions of the medical practice act relating to the examination to be given by the state medical board to osteopaths who desire to practice surgery and obstetrics. The bill proposes that the grades made by an osteopath in the examinations in anatomy, physiology, obstetrics, surgery and diagnosis conducted by the state medical board, shall be averaged

by the state medical board with the various grades received in his examination before the osteopathic examining committee. The bill proposes, too, to eliminate that provision of the present law which provides that an osteopath licensed to practice surgery and obstetrics shall not be permitted to prescribe or administer drugs, except anesthetics and antiseptics. It proposes also that the signature or witness of an osteopathic physician and surgeon shall be accorded the same rights and privileges as are accorded the signature of a doctor of medicine and surgery. S 105, to amend the workmen's compensation act, proposes to make the following occupational diseases compensable, in addition to the diseases now stated in the law: stone workers or grinders' phthisis, pneumoconiosis and silicosis. H 14 to amend the workmen's compensation act, proposes to make the following occupational diseases compensable in addition to the diseases now stated in the law: silicosis, leukotosis, asbestosis and anthracosis.

OKLAHOMA

Bill Passed—S 14 has passed the senate, proposing to authorize the sexual sterilization of habitual criminals and to define as a habitual criminal any person convicted to final judgment three times for the commission of felonies.

OREGON

Bill Passed—H 180 has passed the house and the senate, proposing to limit the distribution of appliances, drugs or medicinal preparations intended or having special utility for the prevention of conception and/or venereal diseases, to licensed physicians and to persons licensed to do so by the state board of pharmacy.

Bills Introduced—S 250 proposes to repeal the laws regulating the sale, distribution and possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act. H 266 proposes that any person using the title "Doctor" in connection with the practice of any form of the healing art shall use in conjunction therewith the appropriate designation of the branch of the healing art he is licensed to practice. H 373 proposes to authorize the state board of health to make such rules and regulations as it deems necessary for the operation of laboratories in which human or animal body fluids, secretions or excretions are examined for the determination of the presence or absence of an infectious agent. Every person, corporation or municipal corporation maintaining such a laboratory is required to register annually with the state board of health. H 377, to amend the laws relating to the state board of health, proposes that the secretary of the board, who ipso facto is the state health officer, shall have a degree of doctor of medicine from a reputable medical school, shall have been licensed to practice medicine in the state, and shall have had at least five years' experience as a full time health officer or two years' residence at a recognized school of public health. The present law merely requires the secretary to be a regularly graduated and reputable physician.

PENNSYLVANIA

Society News—Dr I Newton Kugelmass, New York, addressed the Cambria County Medical Society, February 14, on "Recent Advances in Treatment of Nutritional Disturbances in Infancy and Childhood."

Philadelphia

Society News—Speakers at a meeting of the Philadelphia Laryngological Society, February 5, were Drs Henry Dintenas, "Accidental Injury of the Lateral Sinus", Louis H Clerf, "Cough—From the Rhinological Viewpoint," and Gabriel Tucker, "Difficulty in Swallowing—Esophagoscopic Observations."—The Philadelphia County Medical Society devoted its program to a discussion of the barbiturates. February 13. Speakers were Drs Harold W Jones on "Clinical Manifestations and Treatment of Barbiturate Poisoning and Barbiturate Intoxication," and Thomas Fitzhugh Jr, "Role of Amido-pyridine and Other Medicinal Substances in the Etiology of Agranulocytic Angina" and John Howard Graham M.A., professor of chemistry at Temple University, "Toxicity of Barbituric Acid."

SOUTH CAROLINA

Bills Introduced—S 204 to amend the insurance law proposes to authorize any ten or more persons to associate themselves together as a mutual protection association for the indemnifying of each other for losses on the assessment plan, and not for profit "to insure the lives or health of members against death or disability by accident or disease or

hospitalization benefits." H 21 proposes to create a board of chiropody examiners and to regulate the practice of chiropody [podiatry]. "Chiropody," sometimes called podiatry," states the bill, "shall for the purposes of this act mean the diagnosis, surgical medical and mechanical treatment of ailments of the human foot, except the correction of deformities requiring the use of the knife, amputation of the foot or toes, or the use of an anaesthetic other than local." H 228 proposes that any person or corporation manufacturing, or selling arsenate of lead or other poisonous article, color such article plainly marking on its container in red the word "poison." H 308 proposes to authorize the sexual sterilization of certain socially inadequate inmates of state institutions.

SOUTH DAKOTA

Bill Introduced—S 82 proposes to authorize county sub-commissions for the control of the feeble-minded to order the sexual sterilization of feeble-minded persons they may determine to be capable of procreation.

TENNESSEE

Bills Introduced—S 297, to amend the medical practice act proposes (1) to provide that members of the board of medical examiners be appointed by the governor from a list of names submitted by the Tennessee State Medical Association and (2) that no license shall be revoked until the licensee has been notified in writing of the charges against him and has been given an opportunity for a full and complete hearing, with the right to be represented by counsel. H 473 proposes to make the incurable insanity of either spouse grounds for divorce.

TEXAS

Bill Introduced—H 464 proposes that no hospital shall be exempt from taxation unless it permits its facilities to be available to "each and every reputable physician" licensed by the state board of medical examiners.

UTAH

Bills Introduced—H 114 and S 145 propose to authorize the department of registration to appoint a committee of three to examine applicants for licenses to practice massage and to exempt massage from the definition of the practice of medicine. H 169 proposes to authorize the establishment of a hospital to be called the State General Hospital for the care and treatment of indigent sick.

VERMONT

Bills Introduced—H 203, to amend the osteopathic practice act, proposes to authorize the board of osteopathic examiners to refuse to issue licenses and to revoke licenses for the following causes: (1) conviction for procuring a criminal abortion, (2) obtaining practice or money by false or fraudulent representation, (3) assumption by an applicant or a licensee of a name other than his own and (4) other immoral, unprofessional or dishonorable conduct. The phrase "unprofessional or dishonorable conduct" is to mean (1) advertising which has a tendency to deceive the public, (2) conviction of any offense involving moral turpitude (3) habitual intoxication and (4) habitual use of habit-forming drugs. H 162 proposes to limit the retail sale or distribution to licensed physicians and registered pharmacists of articles or medicinal preparations that may be used as prophylactics or contraceptives. H 161 proposes that the provisions of the pharmacy practice act shall not apply to the sale in properly labeled original packages of the following drugs: bicarbonate of soda, citric acid cod liver oil, epsom salt, magnesium saltpeter, turpentine, quinine, cathartic pills, seidlitz powders, spirit of ammonia and spirit of camphor.

WASHINGTON

Bill Passed—S 32 has passed the house and the senate, proposing to eliminate from the criminal code those provisions prohibiting the possession, sale or other distribution or the use, of contraceptives.

Bills Introduced—S 145 proposes to create a board of physio-medical examiners and to regulate the practice of physio-medicine and surgery. Applicants for such licenses must successfully pass a basic science examination before they may be examined by the board. The bill defines physio-medicine as "that system of medical practice which uses botanical and biological substances and derivatives therefrom for internal and external administration in conjunction with surgery and electro-therapeutical agents and all other manual and mechanical

manipulations for the correction of abnormal or diseased conditions of mind and body.' S 234 proposes that both parties to proposed marriages, as a condition precedent to their right to obtain licenses to wed, present certificates from licensed physicians showing that each is free from contagious or infectious venereal diseases. H 385 proposes that actions for malpractice must be brought within two years, instead of three years, of the accrual of the cause of action. H 397 proposes to prohibit the retail sale and distribution of veronal, barbitol or any of its salts, derivatives or compounds, except on the prescription of a licensed physician, dentist or veterinarian. H 382, to supplement the dental practice act, proposes to make it unlawful for any person, firm, or association engaged in the practice of dentistry to advertise in any manner any price or fee for any service or the price charged for any material to be used in the practice of dentistry.

WEST VIRGINIA

Bills Introduced—H 342 proposes to repeal the laws regulating the possession and distribution of narcotic drugs and to enact what the draftsman of this bill cites as the 'uniform narcotic drug act'. The bill, however, differs from the model uniform narcotic drug act in some important particulars. It omits the provisions in the model bill intended to limit the gross quantity of a habit-forming drug a person can buy in exempt preparations within a period of forty-eight hours. S 69 and H 160 to amend the workmen's compensation act, propose (1) to require the compensation commissioner to pay such sums for medical surgical and hospital treatment as may reasonably be required to relieve an injured employee, the present law limiting such payments to \$800 and (2) to eliminate those portions of the present law which prohibit the commissioner from paying for medical and hospital services furnished an injured workman if the workman is entitled under a contract connected with his employment or by reason of a subscription list, to receive medical, surgical and hospital treatment without further charge to him. S 112, to amend the workmen's compensation act, proposes to make silicosis compensable. The bill proposes to create a "silicosis medical board" to consist of three licensed physicians, to which the compensation commissioner is to refer all claims for compensation on account of silicosis. The board is to investigate, examine and report its findings to the commissioner. S 155 and H 317, to supplement the insurance laws, propose to permit stock companies to incorporate under the general incorporation laws of the state. Companies so incorporated may issue policies providing "every coverage appertaining to accident and health insurance." Specifically they may issue policies providing reimbursement for expenses incident to personal injury sickness or death," but they may issue also policies of accident and health insurance covering personal injury disablement or death by accident disability resulting from sickness." The provisions of this bill may be construed to authorize a corporation organized under it to furnish directly to its policyholders medical, nursing, laboratory and hospital services.

WISCONSIN

Research on Hormones—A grant of \$57,500 from the Rockefeller Foundation has been accepted by the University of Wisconsin to continue research on hormones which is carried on by Dr Elmer L. Serrinhaus, professor of medicine. Frederick L. Hisaw, Ph.D., professor of zoology, and Leon J. Cole, Ph.D. professor of genetics.

Bills Introduced—S 160 makes it unlawful for any person to operate or experiment in any manner whatsoever on any living dog for any purpose other than the healing or curing of such dog. Any person the bill proposes, violating the provisions of this bill shall be punished by a fine of from \$100 to \$500 and/or imprisoned for from three months to one year. A 226 proposes to prohibit a pound master from (1) using or permitting any live animal in his possession to be used for experimental or commercial purposes or (2) turning over any animal in his custody to any person, school, university, research laboratory, or experimental station to be used for medical, scientific or experimental purposes of any nature. A 262 proposes to repeal the laws regulating the sale, distribution and possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act. A 188 proposes to make it the duty of any police officer who has in his custody any person whom he believes to be under the influence of an intoxicant to obtain from such person a sample of his blood or urine, if such sample can be obtained without objection from the prisoner and make or cause to be made within twenty-four hours thereafter a test for the determination of its alcoholic content.

GENERAL

Grants Available for Research—The Committee on Scientific Research of the American Medical Association invites applications for grants of money to aid in research on problems bearing more or less directly on clinical medicine. Preference is given to requests for moderate amounts to meet specific needs. For application forms address the Committee on Scientific Research at 535 North Dearborn Street, Chicago.

Two Free Public Health Surveys Offered—The American Public Health Association and the U. S. Chamber of Commerce are cooperating in an offer of two free surveys in connection with the annual health conservation contests. One will be made in a city and the other in a county or district. The surveys will consist of analyses of the local health programs, the facilities and the extent to which these are meeting public health needs, and the final reports will include recommendations for readjustments or changes. The field staff of the public health association will make the surveys, choosing communities according to their need and the likelihood that they will make effective use of such a survey.

Medical Bills in Congress—Changes in Status S 883 has been reported to the Senate, directing the retirement of acting assistant surgeons of the United States Public Health Service at the age of 64 years (S Rept No 150). H R 5913, the War Department Appropriation Bill, has passed the House. Among other things, this bill authorizes an appropriation of \$70,000 for the library of the Surgeon General's Office. It further proposes to limit the number of medical officers who may draw flying pay to five and to limit the flying pay of all nonflying officers to a maximum rate of \$1,400 per annum. **Bills Introduced** S 1956 introduced by Senator McAdoo, California, proposes to provide for entry upon public lands for the purpose of establishing "health habitations." H R 5594, introduced (by request) by Representative McSwain, South Carolina, proposes to create in the medical department of the regular army a medical auxiliary corps.

Revision of Terminology—At the request of the Anatomical Society of Great Britain and Ireland, the American Association of Anatomists has appointed a committee to consider, with a view to international agreement, a revision of the standard terminology of human gross anatomy (the BNA) which has been in use in American textbooks since its adoption in 1895. The committee, under the chairmanship of Dr Clarence M. Jackson, professor of anatomy, University of Minnesota Medical School is studying both the British proposal and another suggested revision prepared by a committee of the German Anatomical Society. For the benefit of those interested in solution of the problems involved in revising anatomic nomenclature, a triple list of the BNA and the British and the German revisions, in parallel has been prepared. A limited number of copies are available for general distribution and may be obtained without charge from the secretary of the American Association of Anatomists, Dr George W. Corner, University of Rochester School of Medicine, Rochester, N. Y.

Grants of National Research Council—The National Research Council announces that funds for grants in aid of research are now available and that applications for grants must be filed on or before April 1. Action on these applications will be taken about the middle of May. At meetings in November and December 1934 the following grants were made in the field of medical science:

Dr. Garner Howard Bailey, associate professor of immunology, Johns Hopkins University School of Hygiene and Public Health, Baltimore, the heterophile antigens of bacteria.

David M. Greenberg, Ph.D., associate professor of biochemistry, University of California, Berkeley, the effect of diets low in magnesium on Vitamin G requirements.

Dr. Louis N. Katz, assistant professor of physiology, Division of Biological Sciences, University of Chicago, factors operating to modify the coronary blood flow.

Pearl Kendrick, bacteriologist, Michigan Department of Health, Grand Rapids, antigenic properties of bacillus pertussis.

Dr. Albert P. Krueger, lecturer in medicine, University of California, Berkeley, the nature of bacteriophage.

Dr. Orinello R. Langworthy, associate professor of neurology, Johns Hopkins University School of Medicine, Baltimore, control of the urinary bladder by the peripheral and central nervous system.

John P. Quigley, Ph.D., assistant professor of physiology, Western Reserve University School of Medicine, Cleveland, the rate of absorption of oxygen from the intestinal lumen of unanesthetized dogs.

Dr. Harold D. Senior, professor of anatomy, University and Bellevue Hospital Medical College, New York, anomalies of the limb arteries in embryos.

Application blanks for the new grants will be furnished on request to the secretary of the committee, 2101 Constitution Avenue, Washington, D. C.

Successful Corneal Grafting

In 1930-1931 Mr J W Tudor Thomas evolved a successful technic in corneal grafting by experimental work on rabbits. He then applied it to the treatment of dense corneal opacities in man with remarkable success. At the Oxford Ophthalmic Congress last July he demonstrated a successful corneal graft on each eye, apparently the first of the kind on record. This patient, a woman, was recently demonstrated at a medical congress in Boston, Massachusetts. At a meeting of the Section of Ophthalmology of the Royal Society of Medicine, Mr Thomas showed his fifteenth case of corneal grafting in man. The patient, a man, aged 57 suffered at the age of 17 from corneal ulcers, which left central corneal opacities and very defective sight. Seventeen years later, peritomy was performed on each eye. About twenty years ago the eyes became ulcerated again. Last June Mr Thomas performed corneal grafting at the Central London Ophthalmic Hospital. Before operation the right eye showed a dense central corneal opacity, with considerable haze of the surrounding cornea and some degenerative epithelial changes in the opaque area. Vision amounted to finger counting at 15 inches. The left eye had still less vision—only hand movements. There was an extensive central leukoma with some superficial blood vessels passing on to it and a few small interstitial vessels. The periphery of the cornea was hazy. Unless in a familiar place, the patient had to be led about. A donor's eye became available when the right eye of a man aged 60, was excised for choroidal sarcoma. A portion of cornea about $4\frac{1}{2}$ mm in diameter was removed by means of a trephine and scissors. The margin was cut in a shelving manner and the graft placed in a watch glass of sterile olive oil. A larger trephine ($4\frac{3}{4}$ mm) was used to outline the piece to be removed from the middle of the patient's opaque left cornea and two cross sutures were inserted. The removal was then effected with trephine and scissors, the margins being cut shelving. Citrated saline solution and epinephrine were used to ensure freedom from adhesion of the iris. The leukoma consisted of comparatively soft tissue and was not very vascular. After the removal the pupil was seen to be small and in the center of the opening. The graft was laid on, the sutures were tied, 1 per cent scopolamine in olive oil was applied and a shield was placed on the eye, with gauze on the anterior surface. The operation was performed under cocaine anesthesia with premedication by pentobarbital sodium.

After the operation the eye progressed well without pain. There was only a little soft mucoid discharge. On the eighth day the stitches were removed. The graft was well in place, clear and united, flat and round, and the eye was hardly at all red. At fourteen days the graft was clear with one minute white spot on the posterior surface near the lower margin. In the shelving margin of the graft a few small blood vessels took a circular course. From the eighth to the twentieth day the eyes were covered by pads and a bandage, and after that dark glasses were worn. On the thirty-third day vision was 1/60, on the thirty-fourth 2/60 and on the thirty-fifth 3/60. About this time he could read notices in shops at a distance of 2 yards. Four and a half months after operation the graft was clear with a small opacity near the lower margin and a similar but separate nodule on the iris, suggesting that the two were in contact at an earlier stage. He could see and was able to go about London by himself. Six months after operation his vision was 6/60.

Mr Thomas has now treated sixteen cases of corneal opacity by grafting. Five were not really suitable cases. One case is too recent for report. In all the remaining ten suitable cases the graft became united. In one case the graft was successful but the small pupil did not correspond to the center of the graft. Seven cases can be termed "successful," the graft retaining considerable transparency and there being considerable improvement in vision.

Interruption in the Falling of the Birth Rate

Provisional figures for 1934 show an increase of 0.4 per thousand in the birth rate for England and Wales above the low record of 1933 and the only increase since 1920, except in 1928, when a slight rise of 0.1 followed the exceptional fall in the previous year. The figure for 1934 was 14.8 per thousand. The crude death rate was 11.8 and the infant mortality rate (deaths under 1 year per thousand live births) 59, which is 5 below 1933 and the lowest recorded, which was 60 in 1930.

No explanation is given of this slight rise in the birth rate following an almost uninterrupted fall, which has been in progress for more than half a century. In the decade 1871-1880 the annual rate averaged 35.4, and in 1926 it had been almost halved by the figure of 17.8 and in subsequent years more than halved. The rise is probably only a temporary interruption of the long progressive fall. It may be due to the improvement in the industrial situation, which also is only slight. The falling birth rate is also reflected in a volume on housing, just published relating to the census of 1931. A table showing the average size of families gives for 1931, 3.72 for 1921, 4.14, for 1911 4.36. The two-person family now amounts to 21.9 per cent of the total families and the three-person to 24.1 per cent.

National Council for the Disposal of the Dead

The National Council for the Disposition of the Dead, which has been in the course of formation since 1933, has been formally constituted. Lord Horder, who presided, explained that the word "disposition" had been used because it was the officially recognized term. Hygienic disposal of the dead had long been considered one of the fundamentals of public health. Yet though official activity had been extended to drainage, water supply, ventilation, sewerage, purity of food and other problems affecting the health of the community the important matter of the disposal of the dead was left entirely to private enterprise. To remedy this defect a committee representing cremation authorities, undertakers and cemetery superintendents set to work and in 1933 defined their objects as follows: (1) revision and codification of the laws governing the disposal of the dead, (2) preservation of land in the interests of the living, (3) improvement of the status of those concerned with the disposal of the dead, (4) safeguarding of public interests in all matters affecting the disposal. The law today had no relation to the circumstances of our times, and there was pressing need for its revision and codification. The committee had decided that the most important immediate task was to obtain public recognition of the undertaker for the national duty he performed. This could be done through the registration of qualified undertakers, who would observe a high standard of service. Registration would establish a barrier against crime and insure a further means for detecting it. Resolutions were carried for formally constituting the council, with a legal and parliamentary committee.

Road Accidents

In 1934 there were 7,273 persons killed and 231,698 injured in road accidents in Great Britain in which horses or vehicles were concerned. This is an increase on the figures for 1933 which were 7,202 and 216,238 respectively. The number of recorded accidents involving personal injury was 204,800 of which 7,088 were fatal. The corresponding figures for 1933

were 191,782 and 7,001. There was thus an increase of 68 per cent in the total number of accidents (as compared with an increase of 4.2 per cent last year) and an increase of 1.2 per cent in the number of fatal accidents (as compared with an increase of 7.9 per cent last year).

The figures for London show an increase in the number of persons injured and a decrease in the number of persons killed the totals for 1934 being 59,029 and 1,418 respectively while the figures for 1933 were 56,912 and 1,441.

Warning Against American "Interviews"

The medical profession in France has noticed that certain American lay periodicals carry advertisements in which some physicians, chiefly those connected with large Paris hospitals endorse the particular product advertised and even allow their photographs to be published. As a result of the growth of this method of exploitation of the medical profession not only of France but also of Germany and Austria an effort is being made in France to end this unethical practice. The following article appears in the *Presse medicale* January 12, signed by one of its editors Dr. P. Desfosses.

"The sale of certain pharmaceutical specialties to the general public through the medium of advertisements in the daily press has assumed considerable importance from the financial point of view for the past thirty-five years. Those who advertise their products advise the public to use the particular preparation without consulting a physician. Nevertheless whenever a report is made by some member of the medical profession before a society, advantage is taken of such communications to incorporate them in the advertising inserted in journals read by the laity. Some of these papers read at medical society meetings cannot be used for advertising purposes so a new method has been devised, which consists in sending a suave representative to 'interview' the various professors in the larger medical centers of Europe on some question of medical practice and then to utilize these conversations in altered form as recommendations of the particular drug or food product which the interviewer represents. The interview is then published and the various titles held by the professor who has been interviewed and even his photograph added to show the genuineness of the endorsement. The photographs of all leading medical men on the continent of Europe are on sale at the medical bookstores, so that it is unnecessary to ask for a photograph for insertion in the advertisement.

'The minister of foreign affairs of France has recently sent to the society that has charge of foreign medical relations a large number of clippings of such advertisements from American periodicals, which no doubt have made a bad impression on the medical profession of the United States and Canada as to the ethical standing of those who have allowed themselves to be 'interviewed' by representatives of American food products and others. The fear is expressed that those who see this publicity do not realize that the photographs and accompanying endorsements have been published without the consent or knowledge of the respective medical men. Hence the minister of foreign affairs warns the profession in France against these suave interviewers, who by flattery and under the cloak of a desire to benefit humanity seek to secure endorsements which are altered so as to make good publicity. Such a practice is considered very unethical by the French medical profession."

Resistance to Insulin

In the January *Gazette medicale de France*, the question of resistance to insulin is discussed by Labbe and Boulin, who have a service that specializes in the treatment of diabetes at a public hospital of Paris. The cases that are considered resistant to insulin are not nearly so common as one would think. Most of the reported cases of this kind are the result of the faulty use of insulin. The patient is frequently to blame

because the diet is not followed as it should be. On the other hand, the physician is to blame often because a diet that contains too much carbohydrate is ordered. In some cases the doses of insulin are not high enough or the injections are given at too frequent intervals. Again, insulin is prescribed in cases of nondiabetic glycosuria, in which its use is contraindicated. Excluding all these cases, is there such a condition as insulin resistance? In order to establish 'insulin resistance,' two conditions must be complied with.

First, that the insulin has no effect on the blood sugar. This is the essential feature indicating insulin resistance.

Second if the diet is an unvarying factor and the blood sugar and acetonuria also are constant, the administration of insulin should not determine any decrease in either the glycosuria or the acetonuria.

There are few cases in which both of these conditions of insulin resistance are found hence one can consider insulin resistance very rare. Labbe and Boulin have observed only one case in which insulin had no influence on the blood sugar, glycosuria and acetonuria. They concede that one may encounter cases in which there is a partial insulin resistance, in which the hypoglycemia insulin test reduces the blood sugar by only 49 per cent as an average instead of the maximum of 81 per cent and secondly, that the quantity of carbohydrates that a unit of insulin will metabolize is much less than a gram instead of the normal 15 Gm. It is well known that larger doses of insulin are needed in cases of diabetes complicated by infection than when the latter does not exist. A certain degree of insulin resistance is observed also in cases of diabetes associated with hypophyseal growths, in exophthalmic goiter or in cirrhosis of the liver. Aside from these instances of partial insulin resistance, too much importance ought not to be attributed to the frequency of the condition. Aside from cases of diabetes complicated by infection, insulin resistance for all practical purposes occurs but rarely.

Paroxysmal Hypertension

Two recent meetings of the society composed of chiefs of medical services of the large Parisian public hospitals (*Societe medicale des hopitaux de Paris*) were devoted to papers on this relatively new clinical entity.

Donzelet divided paroxysmal hypertension into three clinical groups. 1 Cases in which it appears in individuals suffering from permanent hypertension. 2 Those in which there is a well defined clinical syndrome. 3 Those found in certain patients with adrenal tumors. In the first of these the attacks of paroxysmal rise of blood pressure above the average found in the particular case of hypertension may pass unnoticed unless the blood pressure happens to be observed during such an exacerbation. In other cases, one observes definite evidence in the form of polyuria, cramps in the calves of the legs, angina-like pains, severe headache, and a syndrome called "cerebral eclipse," in the form of amnesia, transitory amaurosis or aphasia, word blindness, deafness or paralysis. These "eclipses" are interpreted as due to an arterial spasm.

A paroxysmal hypertension can frequently provoke serious accidents in cases of hypertension, in the form of cerebral hemorrhage or acute left ventricle insufficiency. Such paroxysmal exacerbations are hence a constant menace in hypertension cases. In the second group one finds paroxysms of hypertension associated with lead poisoning, eclampsia, irritations of the peripheral sensory nerves, and so on. The familiar lead colic occurs during such a paroxysmal rise of blood pressure and ceases when the latter falls. The same is true of some of the cerebral symptoms observed in cases of lead poisoning. Convulsions in eclampsia synchronize with transitory rises of blood pressure. During the last twelve years the attention of clinicians has been called to the fact that tumors involving the

chromaffin cells of the adrenals are accompanied by crises of hypertension, which may be very severe. Donzelet describes such a case in which the attacks occurred daily. This paroxysmal hypertension is accompanied by albuminuria and a rise in blood urea and at times by a hyperglycemia with or without concomitant glycosuria. There is also an increase in the number of red and white corpuscles in the blood. If the adrenal tumor is not removed, the hypertensive attacks increase in frequency, there is accentuation of the disturbances of elimination, and death occurs as the result of a vascular rupture or acute pulmonary edema. One should always suspect a neoplasm of chromaffin origin whenever such paroxysmal hypertensive crises occur. The only available treatment in the first two groups is to attempt to lessen the severity of the attacks by the administration of barbiturates, opiates, organic nitrates and bleeding.

Benard and Merklen discussed the relation between the carotid sinus and changes in blood pressure. In 1923 Hering called attention to a slight swelling at the point of origin of the internal carotids, which plays an important part in the regulation of arterial tension. His observations have been confirmed by others, including Benard and Merklen. Stimulation of this carotid sinus is followed by a fall in blood pressure, and suppression of its physiologic action is followed by hypertension and tachycardia. The nerves of Hering, as they are termed, which arise from this center, are veritable "brakes" on arterial tension. There exists a "permanent sinocarotidian depressor tonus," which assures the regulation of blood pressure by acting as a "brake" against the constant tendency on the part of the organism toward hypertension. It is tempting to ascribe clinically pathologic changes in arterial tension to functional disturbances of this carotid sinus and sensitive cardio aortic zone, which latter heretofore has been considered to play the chief part in alterations of blood pressure. Clinically, one encounters many objections to the theory that the carotid sinus regulates blood pressure, hence the possibility of treating cases of permanent hypertension by operations on such a center does not offer as good prospects as that of drugs that will influence this carotid sinus center.

Mouquin stated that paroxysmal hypertension is due to a sudden disturbance of the regulatory mechanism of arterial tension. For practical purposes, one could place the cases of paroxysmal hypertension under three etiologic headings. First, those of central origin in which, as a result of an acidosis or of an anoxemia or a brain tumor there is a stimulation of the hypertensive tonus of the vasopressor centers. Second, those of cranial nerve origin. Of recent years, two cranial nerves have been considered as responsible, the fifth in cases of zona and the tenth in a cancer of the esophagus involving also the larynx, and also in a case of lymphosarcoma of the mediastinum. Third, those of adrenal tumor origin. These clinical observations are the most common and the most characteristic. These tumors seem to act by an excessive, either gradual or sudden, discharge of epinephrine secretion into the blood stream which causes a dysfunction of the regulatory mechanism for arterial tension, thus resulting in an intense vasoconstriction and subsequent rise in blood pressure. Such a hypersecretion of epinephrine has never been demonstrated. Stimulation of the splanchnic nerves has also been held responsible for the hypertension in these adrenal tumor cases. Further observations are needed as to the part played respectively by the adrenal and the splanchnic. Perhaps one will find cases of tumors of paraganglionic structures, which, with the adrenals, form the chromaffin system. One should always keep in mind clinically the distinction between cases of permanent and those of paroxysmal hypertension.

Marcel Labbe had previously reported two cases of paroxysmal hypertension occurring in association with adrenal tumors.

He corroborated the hyperadrenalinemia theory of the previous speaker and said that methods for determining the amount of epinephrine in the blood are still imperfect. One does not always find renal lesions in cases of paroxysmal hypertension, and, when they occur, they do not resemble those of a typical nephritis.

De Gennes, who did not agree with this view, thinks that there is a disturbance of renal function during every attack of paroxysmal hypertension and that they persist for some time afterward. In certain cases the paroxysmal hypertension is followed by a true chronic nephritis. On the other hand, one sees cases of even advanced permanent hypertension without disturbances in renal function.

Laubry agreed with Donzelet and de Gennes as to the absence of any constant relation between hypertension and nephritis. A paroxysmal hypertension, if the attacks occur frequently enough, may undergo transition into a permanent hypertension. In such cases the renal lesions as found at necropsy are either absent or only slight.

Society for Anesthesia Formed

Although there are almost innumerable societies, no special one in France for the study of anesthesia had been formed until recently, when such a society was organized with Professor Fargue as honorary president and Professor Gosset as president. The society will hold four meetings a year in Paris and an extra session in the fall during the French Surgical Congress. A special journal devoted to anesthesia will be published.

Prof Caesar Roux of Lausanne

Although not a French surgeon, Professor Roux, who died at Lausanne at the age of 77 years, was so active in the surgical congress held annually here that he was regarded as an international figure. The city in which his clinic was situated, although not a portion of France, is in that portion of Switzerland where only French is spoken. His clientele included patients from all countries, especially France and the United States. His skill as an operator and his equal treatment of the rich and the poor have commanded the admiration of all.

BERLIN

(From Our Regular Correspondent)

Dec. 24, 1934

The German Dermatologic Society

After the omission of several annual sessions, the Deutsche Dermatologische Gesellschaft met recently in Berlin, under the chairmanship of Professor Zieler of Würzburg. The first paper was presented by Professor Bering of Cologne on "Scientific Bases for the Diagnosis of Industrial Diseases of the Skin and for the Estimation of the Degree of Disability." In the official list of occupational diseases of 1929 are found all the occupational dermatoses entitling the patient to compensation. Eczemas are the most common manifestation. Occupational eczema is an allergic disease. In inquiring into the right to compensation, if the presence of an occupational eczema is recognized, an existing idiosyncrasy must not be overestimated. The stronger the sensitizing power of a substance is, the more likely the appearance of an occupational eczema. The longer a single hypersensitiveness is fanned, the more likely general sensitiveness will result. Careful skin tests are needed. A positive test proves sensitization but a negative test does not justify rejection of an occupational eczema. The substances used by the patient in his occupation must, if necessary, be examined and tested. The diagnosis "chronic eczema" is justified after a duration of eight weeks and the diagnosis "chronic recurrent eczema" after an occupational eczema has appeared three times. A reduction of the number of cases of

occupational eczema may, in the opinion of Bering, be attained by excluding all persons with idiosyncrasies (allergic and seborrheic persons) from occupations in which strongly sensitizing substances are used.

Professor Curschmann brought out in a paper that the precise estimation of the degree of disability is hampered by the diagnostic difficulties. Cutaneous disease may be the sole expression of an occupational injury or only the symptom of a systemic disease as a result of occupational injury. Occupational acne is promoted by disturbances of metabolism, an undermined general condition, and sensitive skin. In Curschmann's opinion, however, the paroxysmal appearance of an occupational acne is the expression of an already acquired sensitiveness. Among workmen one often observes eczemas that are not occupational eczemas. Compulsory declaration of all substances used in a given industry should be demanded, together with a complete statement as to the possibility of injuries and the necessary preventive measures, furthermore hygienic measures should be taken, proper skin and wound treatment, and, if need be, protection of the skin with zinc ointments. General skin tests before workmen are employed cannot as yet be demanded. The number of occupational skin diseases is small and has been decreasing in recent years.

The interpretation of psoriasis as a primary lipoidosis, as set forth by Grütz, has not found as yet any uniform recognition. In psoriasis, according to Grünberg of Halle, a subordinate function of the adrenal cortex has causal importance. By the application of suitable therapy, manifestations of psoriasis were eliminated in a striking manner, the vitamin C content of the remedy is said to have played no part.

Lomholt of Copenhagen reported his results with chaulmoogra oil in other than leprosy disorders, for example lupus erythematosus and mycosis fungoides. In lupus vulgaris the results were nil.

Gold therapy in syphilis, according to Heuck and Vonkennel of Munich, has given good serologic results, it may gain importance also in resistance to therapy, in seroreaction remaining stubbornly positive, and as a substitute for fever therapy. An oily preparation was employed. But more observations must be reported before any definitive statements can be made.

In the treatment of lupus, Stühmer regards the present method as adequate. According to Lomholt, Denmark has made greater progress in this field than Germany, owing to more intensive study of lupus patients. Hospital treatment is commonly employed from the start (Finsen light locally, general light exposure and administration of vitamin preparations).

The Examination of Aviators

In the Eppendorf Hospital in Hamburg there was established, years ago, an institute to deal with the medical problems of aviation (Institut für Luftfahrtmedizin). Since practical aviation makes special demands on medical research and cooperation, the testing of the aptitude of aviation candidates was organized in this institute in a systematic manner. Night flying and flying through fog, altitude flights, diving and stunt flying are limited by the capacity of the human body to endure hardships. These problems the aviation physician must study in detail. While physical fitness is indispensable to the aviator, the most important matter in his success is such qualities as mental alertness and firmness of character. A candidate's aptitude, as Dr. Lottig brought out in addressing the Hamburg Medical Society, must not be based, as was formerly done, on mechanical and psychotechnical experiments but must take into account the candidate's personal qualities as learned from most intimate association with him under varying circumstances. The effects of great altitudes on the mental behavior of a person must not be overlooked. Excitation and mild disorganization accompanied by a certain lack of judgment and

resoluteness may, under some circumstances, be a serious danger for the aviator. These conditions can be studied, in testing the aptitude of aviation candidates, in the subpressure chamber.

Continuation Courses for Physicians

A new kind of continuation courses for physicians will be organized the coming spring, in the Rudolf Virchow Hospital in Berlin. The courses will provide whole-day instruction at the bedside and in the laboratory, so that practitioners will have the opportunity to renew their experiences with hospital routine. They will participate also in the seminar drills that the head physicians will hold on the principles of diagnosis and therapy. It is also planned to give certain lectures on subjects selected by the visiting physicians. The physicians taking the continuation courses may choose an institution where they will work or they may divide their activities among several institutions. The participants can secure room and board in hospitals for 2.50 marks (\$1) a day. Like all municipal continuation courses for physicians given in Berlin, these courses will be open only to physicians of Aryan race.

The Number of Miscarriages

Since 1924 the city of Lübeck has collected systematic statistics in regard to miscarriages on the basis of confidential report cards filled out by physicians, midwives, hospitals and the office of the Ortskrankenkasse. These interesting figures are not entirely complete, but they are fairly comprehensive. According to these statistics, the number of miscarriages in 1932 was 1,036 or almost two thirds of the notifiable living births and stillbirths combined. The proportion of miscarriages in relation to the number of announced pregnancies (that is, the notifiable pregnancies and the miscarriages taken together) was in 1924, in which year the absolute number of miscarriages was 434, 16.8 per cent. In 1927, owing doubtless to a more complete registration, the proportion increased to 33.6 per cent, the absolute number being 947. Then, during the more favorable economic conditions that followed, it receded a little (30.9 per cent in 1929) and later, during the economic crisis, rose again to 33.7 per cent in 1931 and to 39.4 per cent in 1932. The proportion was 35.6 per cent for married persons in 1932 and 56 per cent for unmarried persons. Classification of the miscarriages (so far as possible) revealed that in 1932, among married persons, 53.8 per cent of all miscarriages were reported as the first, 26.9 per cent as the second, 9.9 per cent as the third, and 4.6 per cent as the fourth miscarriage. Among unmarried persons the first miscarriages predominated, with a proportion of 84.2 per cent, the second miscarriages were represented by 12.5 per cent.

New Convalescent Centers

Under the name "Parkherstellingsoorden" Dr. Hartogh of Amsterdam has founded a society to provide suitable centers for convalescents. He observed that many patients, on being discharged from hospitals, supposedly cured were still in a physical condition that precluded their resuming their occupation, and it was for this class chiefly that the new centers were founded. Many patients without resources are allowed the privileges of the centers free of charge. The city of Amsterdam has placed at the disposal of the society large parcels of ground, on which temporary shelters have been erected, where convalescents may spend the day, from 9 a. m. to 5 p. m. New guests are examined, on first entering, by a physician without charge. Infectious and tuberculous patients are not admitted. Patients spend their time reading, resting in comfortable chairs or doing bits of handwork. The work

of the society has been taken up by other cities and similar centers have been created.

Because of the low prices charged and frequent remission of all charges, these societies often get into debt, in which event the Red Cross, the city of Amsterdam and many private donors come to the rescue.

Traffic Accidents

Table 1 gives a survey of the traffic accidents causing deaths in the Netherlands in 1931

With 491 deaths, automobile accidents occupy first place. It is easy to understand why the greatest number of deaths occur among children under 10 years of age, and why boys are in the majority.

Accidents are not more frequent, in proportion to the population, in the large centers than in the small towns. The mortality rate in cities of more than 100,000 population was 5.9 per hundred thousand inhabitants, in cities of from 20,000 to 50,000, 7.6 per hundred thousand and in cities of 5,000 or less, 6.2.

As the best prophylactic measure, closer supervision of children is recommended, also previous examination of drivers, although it is admitted that experienced drivers, as well as beginners, are involved. A psychiatric examination of professional drivers has been proposed. The length of the working

TABLE 1—Fatal Traffic Accidents in the Netherlands

Age of Victim		Train	Tram way	Auto cars	Other Vehicles	Totals
1-4 yrs	Male	3	4	32	9	48
	Female		3	17	3	23
5-9 yrs	Male	2	3	56	9	70

day and condition of the vehicles are to be considered. Proper police control and adequate lighting of streets also enter into the problem.

The Crusade Against Trachoma

Trachoma may be regarded as endemic in the Netherlands. It appears, however, that, owing to an effective campaign carried on in recent years, this disease is about to disappear—as far as Amsterdam is concerned, at least. In 1870 45 per cent of the Jewish school children were trachomatous. Aroused by the frequency of this disease, the ophthalmologists launched a campaign of hygienic education. In 1913 there were still about 3,000 children affected. The authorities then appointed a commission to organize a systematic crusade against the disease.

In the report presented for the period 1914-1917 there were 8.8 per cent of the Jewish school children affected, as against only 0.6 per cent of the non-Jewish children. The commission found that it is not the school that plays the principal part in

propagating the disease, but the family environment. The commission proposed to the municipal authorities the following means of defense: (1) the installation of a polyclinic in the Jewish quarter, where the patients could go for treatment, (2) appointment of an ophthalmologist for the regular supervision of the schools, (3) regular treatment by the school physician of all trachomatous children attending the schools. Those not submitting to this treatment were to be excluded from courses of instruction.

TABLE 2—Incidence of Trachomatous Disease in the Elementary Public Schools

Year	Jews per Cent	Non-Jews per Cent
1914	56.2	5.2
1918	52.1	6.1
1923	39.1	1.8
1927	14.4	0.9
1928	10.1	1.0

TABLE 3—Total Number of Trachomatous Patients in the Jewish Schools with 2,000 Pupils

Year	No. of Patients	New Cases
1918	176	57
1920	170	30
1921	177	23
1927	59	6
1928	44	2

As a result of these measures, all the children were brought under treatment and most of them were cured. The duration of the treatment ranges from one to four years, depending on whether the children come regularly for treatment, and also on the degree of cleanliness in the home surroundings.

Tables 2 and 3 reveal in a graphic manner the retrogression of trachoma among the children in the public schools.

These figures justify the hope that, ten years from now, trachoma will have entirely disappeared from Amsterdam. It would be dangerous, however, to abandon treatment at this juncture.

VIENNA

(From Our Regular Correspondent)

Jan 2, 1935

Is Cancer on the Increase?

Contrary to the assumption that malignant disorders have undergone a marked increase in recent decades, Dr. Bashford of the Imperial Cancer Research Fund expressed the conviction, twenty-five years ago, that this view is incorrect, and since then other statisticians have supported his assertion. The Vienna investigator Dr. Peller, who has made an extensive study of the question, declares that the apparent increase is due to the marked increase in the average age of the population. Owing to the reduction in the birth rate, a considerable modification of the representation of the respective age groups of the population has occurred. In 1900 there were thirty-six births a year per thousand of population, but in 1930 only 17½. The progress of hygiene, which has markedly reduced the incidence of smallpox, typhoid and cholera and likewise diminished the mortality of tuberculosis and children's diseases, has brought about an increase in the representation of the older age groups. The average life expectancy has increased, during this period, by not less than fifteen years. In 1900 there were 125 persons more than 50 years old per thousand of population, by 1930 the number had increased to 205. Thus many more persons belong to the age groups menaced by cancer than thirty years ago. The statistics must therefore be so elaborated that only like age groups are compared, that is, a principle of equalization must be applied. If that is done the remarkable

fact is developed that cancer mortality in the middle age groups has not increased but, on the contrary, shows a distinct retrogression. That is shown clearly in the table that Dr Peller has prepared for Vienna. The table shows the number of deaths from cancer per 10,000 of population in the various groups

Periods	20-30	30-40	40-50	50-60	60-70	70 and above
1901-1905	0.89	3.6	15.45	43.45	90.62	122.0
1906-1914	0.93	3.2	13.90	41.60	88.8	116.9
1919-1923	0.97	2.9	11.35	39.9	85.6	124.7
1928-1929	1.06	3.0	11.25	40.90	104.1	159.8

It will be seen that the mortality has increased only in the 20-30 age group and in the age groups beyond 60. The first group, however, has little significance, since cancer in these years is rare. The retrogression in the case of women is more significant. Only from the sixtieth year in men and from the sixty-fifth year in women is an increase to be noted in the standardized table, but improvements in diagnosis make the increase appear greater than it really is. The actual retrogression of cancer mortality in the middle age groups is greater than the statistics reveal. Similar results have been reached for Switzerland, America and Germany as Dr Fritz Greger shows in the work cited. These investigations establish the fact that cancer mortality is not increasing. It is true that there appears to be a shifting in the localization of cancer in that the cancer cases more accessible to treatment have become more frequent (skin, tongue). It is also certain that cancer is diagnosed more frequently in well-to-do circles than formerly but this is due to the fact that in these circles medical care has improved. With the increase of early diagnosis the prospects of a cure are increased. Dr Greger emphasizes however that, just as infectious diseases present wavelike fluctuations neoplasms appear to show periods of increase and decrease in cycles of from sixty to eighty years. As for the special conditions obtaining in Austria, it must be borne in mind that 30 per cent of the population of the republic is massed in the city of Vienna, where the diagnosis of cancer is much easier than in the rural sections. Hence it is evident that in Vienna the number of cancer cases diagnosed will show a higher per capita basis than Austria as a whole. Vienna has almost 34 per cent of all the cancer cases but only 30 per cent of the population of the republic. In cancer about 75 per cent of the deaths occur after the fiftieth year of life, while in tuberculosis they occur before that age, but numerically the number of deaths from tuberculosis is less than the number due to cancer. With a better understanding by the public, the early recognition and cure of malignant disease will be advanced so that the diagnostic and therapeutic successes (surgery and ray treatment) will have a favorable effect on the mortality.

Pay Patients in the Ambulatoriums

The complaints against the ambulatoriums have to do primarily with the many patients in them who are able to pay ordinary fees. The fees thus lost during the year by the practicing physicians represent large sums, the loss being felt especially by the specialists. The League of Vienna Specialists has therefore sent a request to the directors of the Vienna hospitals that they cease to accept such patients but refer them to the private specialists, on the ground that it is not the purpose of the ambulatoriums to render gratuitous medical aid to pay patients. Petitions were addressed also to the physicians in the provinces, urging them not to send to the ambulatoriums patients they wish to be subjected to a careful examination but to refer them to private specialists. Suggestions made by the league for the remedying of the conditions provoking complaints were to the effect that every patient who visits the ambula-

toriums be subjected to careful control before being admitted to examination or treatment. Only patients without funds and those who can present a recommendation from their panel physician and a confirmation from their *krankenkasse* should be admitted.

Use of Sodium Citrate in Hemophilia

At a recent session of the Vienna Medical Society, Dr Schürer reported the good results that he had seen in grave hemorrhages following extractions of teeth from the use of a combination of blood transfusion with subcutaneous injection of a 3.5 per cent solution of sodium citrate. Also in other cases of grave hemorrhages from the kidney, following traumas this medication offers in hemophilia the best prospects for a prompt control of the bleeding. The effect is brought about by a reduction of the usually lengthened coagulation period. The normal coagulation period is from four to eight minutes but in the cases observed by Schürer he observed before the injection twenty-one, after the injection sixteen, and on the day of the transfusion thirteen minutes. A blood transfusion should be combined with the sodium citrate. The speaker introduced a man aged 34 who was known as a hemophiliac subject and in whom following a tooth extraction, a grave submucous bleeding in the mouth and a hematoma of the face developed. In spite of all various preparations applied, the hematoma assumed huge proportions and dyspnea appeared. After a venesection of 800 cc a transfusion of 600 cc was given and the sodium citrate was injected daily. The effect was excellent. From 10 to 20 cc should be injected once a day—with children one may begin with 5 cc—but always combined with a blood transfusion. Blood transfusion appears to be the sovereign remedy in hemophilia, but its effects are greatly enhanced by a preceding injection of sodium citrate.

Prof Hans Lorenz

A few days ago Prof Dr Hans Lorenz of the Spital der Kaufmannschaft (not to be confused with the orthopedist Prof Dr Albert Lorenz or his son Adolf) brought his life to a close by his own hand at the age of 59 years. Financial difficulties appear to have been the chief cause. A short time before his death he performed a difficult operation with success. Professor Lorenz was noted for his skill and rapidity in operating which were especially valuable in connection with abdominal interventions, his chief field of activity. He did not publish many articles but before the medical societies he demonstrated many interesting cases. As a young physician he became "assistant" in the Chirurgische Klinik in Vienna, where his brilliant work in the surgical field soon attracted attention. In Hochenegg's *Handbuch der Chirurgie* he prepared the chapters on abdominal operations.

Marriages

MARVIN L. LATIMER, New Haven, Conn., to Miss Mildred Stansill of New York, in Norfolk, Va., Dec 21, 1934

BADIE T. CLARK, Rocky Mount, N. C., to Miss Margaret Page Smith of Atlanta, Ga., January 19

FREDERICK B. HAAR, Greenville, N. C., to Miss Nell Venable Hubbard of Wilmington, January 16

DUNCAN ROLAND McEACHERN to Miss Eloise M. Shepherd, both of Richmond, Va., January 23

ROBERT H. WISEHEART, North Salem, Ind., to Miss Betty Ramey of Indianapolis, January 5

DONALD BROCK KOONCE to Miss Louise Bellamy Wood, both of Wilmington, N. C., January 19

JOHN M. BREWER to Miss Jean Reynolds Culvera, both of Kershaw, S. C., January 12

MARY ELIZABETH LEHMAN to Mr. Wallace Windus, both of Bristol Pa., Nov 24 1934

Deaths

Granville MacGowan ♂ Los Angeles, University of Pennsylvania Department of Medicine, Philadelphia, 1879 Member of the House of Delegates of the American Medical Association, 1909-1911, and chairman of the Section on Genito-Urinary Diseases, 1914-1915, emeritus professor of surgery, University of Southern California School of Medicine professor emeritus of urology, College of Medical Evangelists, member and in 1912-1913 president of the American Urological Association, fellow of the American College of Surgeons, past president of the California Medical Association and the Los Angeles County Medical Association, one of the organizers and formerly member of the health department of Los Angeles and for four years health commissioner, one of the founders and for many years chief of staff of the California Hospital, aged 77, died, January 31, of arteriosclerosis and chronic myocarditis

Thomas James O'Brien ♂ Boston, Harvard University Medical School, Boston, 1899 also a pharmacist taught analytic and organic chemistry at the Massachusetts College of Pharmacy, 1901-1905 a trustee, 1907-1912, and dean, 1911-1912 since 1920 professor of clinical medicine, Tufts College Medical School, in 1914 assistant visiting physician at the Boston City Hospital, from 1919 to 1931 secretary of the medical staff, from 1932 to 1934 member of the senior staff and later appointed consulting physician consulting physician at St Elizabeths Hospital, Boston Marlboro (Mass) Hospital and the Leonard Morse Hospital, Natick, aged 62 died, February 5

Alonzo Marston Garcelon, Lewiston, Maine, College of Physicians and Surgeons Medical Department of Columbia College, New York, 1876 was a Trustee of the American Medical Association, 1883-1901, and in 1901 was elected Vice President formerly state senator and member of the state legislature, at one time mayor of Lewiston and member of the board of education on the staff of St Mary's General Hospital, aged 83, died, January 14, of acute dilatation of the heart and hepatitis

Daniel Hunt Fuller ♂ Philadelphia Harvard University Medical School, Boston, 1891 member of the American Psychiatric Association and the New England Society of Psychiatry, associate in psychiatry University of Pennsylvania Graduate School of Medicine, on the staffs of the Pennsylvania Hospital and the Pennsylvania Hospital Department for Mental Diseases aged 70 died, February 1, of carcinoma of the pancreas

Norman Charles Goodwin, Richmond Hill N Y Albany (N Y) Medical College, 1907 member of the Medical Society of the State of New York on the staffs of the Jamaica Hospital, Richmond Hill the Mary Immaculate Hospital and the Queensboro Hospital for Communicable Diseases Jamaica aged 53 died, January 19, of infectious arthritis and cerebral arteriosclerosis

Lewis E. Maire, Grosse Pointe, Mich Detroit Medical College, 1881, member of the Michigan State Medical Society and the American Academy of Ophthalmology and Oto-Laryngology, past president of the Wayne County Medical Society, formerly member of the board of education and board of health, aged 79, died, January 9, of carcinoma of the prostate.

Ernest Marsh Poate ♂ Southern Pines, N C., Cornell University Medical College, New York 1906, also a lawyer member of the American Psychiatric Association, formerly professor of psychiatry Duke University School of Medicine, Durham, served during the World War aged 50, died, February 1, of pneumonia and pulmonary tuberculosis

Sidney Walker, Dublin, Ga., Hospital College of Medicine, Louisville, Ky., 1904, member of the Medical Association of Georgia past president of the Laurens County Medical Society served during the World War, formerly on the staff of the Claxton Sanitarium aged 55, died, January 22, at Piedmont Hospital, Atlanta, of atrophic cirrhosis of the liver

Harry Samuel Wagner ♂ Pocasset Mass University of Michigan Department of Medicine and Surgery Ann Arbor 1903, fellow of the American College of Physicians, superintendent of the Barnstable County Sanatorium aged 57 died February 8 in the Baker Memorial Hospital Boston, of carcinoma of the urinary bladder

William J. Herman ♂ Boston Harvard University Medical School, Boston 1920 member of the American Neurological Association and the American Psychoanalytic Association instructor in psychiatry at his alma mater on the staff of the Massachusetts General Hospital aged 43 died January 26 of coronary arteriosclerosis

William R. Stringham ♂ Cheboygan, Mich., Michigan College of Medicine, Detroit, 1884, also a pharmacist, past president of the Cheboygan County Medical Society on the staff of the Petoskey (Mich.) Hospital, aged 77, died, January 31 in the Lockwood Hospital, Petoskey, of carcinoma of the sigmoid

William Edwin Fellows, Bangor, Maine, Hahnemann Medical College of Philadelphia, 1876, member of the Maine Medical Association, past president of the Penobscot County Medical Society, on the consulting staff of the Eastern Maine General Hospital, aged 83, died, January 18, of arteriosclerosis.

John Willingham Du Pree, Greenville, S C., Medical College of the State of South Carolina, Charleston, 1913, member of the South Carolina Medical Association, aged 47, died, January 19, in the Greenville City Hospital, of coronary thrombosis and essential hypertension

Dowdell M. Jordan, Oglesby, Texas, Tulane University of Louisiana Medical Department, New Orleans, 1893, member of the State Medical Association of Texas past president of the Coryell County Medical Society, aged 77, died, January 2 of lobar pneumonia

Nathan R. Phillips, Piper, Ala., University of the South Medical Department, Sewanee, 1901, member of the Medical Association of the State of Alabama past president of the Bibb County Medical Society, aged 57, died, Dec 19, 1934, of cerebral hemorrhage

Herbert Theodore Wagner ♂ Indianapolis, Indiana University School of Medicine Indianapolis, 1908, served during the World War, aged 48 on the staff of the Methodist Episcopal Hospital, where he died, January 30 of cerebral hemorrhage

Florence Vincent Guinee, New York Fordham University School of Medicine, New York 1921, member of the Medical Society of the State of New York, on the staff of the Lenox Hill Hospital, aged 38, died, February 5, of nephritis and heart disease

Joseph Taney McGinity ♂ Springfield, Mass., University of Vermont College of Medicine Burlington, 1905 member of the Vermont State Medical Society aged 54, on the staff of the Mercy Hospital, where he died, Dec 24, 1934, of heart disease

Samuel Polk Vineyard ♂ Amarillo Texas, Medical-Chirurgical College of Kansas City, 1900 past president of the Potter County Medical Society, aged 58 on the staff of the Northwest Texas Hospital, where he died, Nov 28, 1934

Franklin George Warner, Peterboro, N H Albany (N Y) Medical College, 1892, member of the New Hampshire Medical Society on the staff of the Peterboro Hospital, aged 71 died Dec 25, 1934, of carcinoma of the pancreas

Harold Johnson Weaver, Hamptonville, N C., Jefferson Medical College of Philadelphia, 1925, member of the Medical Society of the State of North Carolina, aged 37 died, January 14, in the Davis Hospital, Statesville, of pneumonia

Joseph Claybaugh Smith, Grants Pass, Ore., State University of Iowa College of Medicine, Iowa City, 1889, county health officer formerly mayor, state senator and member of the state legislature aged 75, died, Dec 9, 1934

James L. Turnbull, Vancouver, B C., Canada Victoria University Medical Department, Coburg, 1889 University of Toronto Faculty of Medicine, 1889 fellow of the American College of Surgeons, aged 72, died, Dec. 26 1934

Hjalmar Kylberg, Merced, Calif., California Medical College, San Francisco 1893, member of the California Medical Association, past president and secretary of the Merced County Medical Society aged 69, died, Dec. 30 1934

Edwin Merriman Brown, Sheldon Vt. University of Vermont College of Medicine, Burlington, 1879, member of the Vermont State Medical Society, formerly state senator, aged 79 died, February 3 of arteriosclerosis

Frank Marberry Acree, Dover, Tenn., Kentucky School of Medicine, Louisville 1889 aged 78, on the visiting staff of the Clarksville (Tenn.) Hospital, where he died, January 29 of senile gangrene with arteriosclerosis

Charles Lucien Lavender, Columbia, Mo., Missouri Medical College, St. Louis, 1885, member of the Missouri State Medical Association, formerly coroner of Warren County aged 74 died, Dec. 3, 1934, of heart disease

Walter Evan Lee, Clearwater Fla. Maryland Medical College Baltimore 1905 Hahnemann Medical College and Hospital of Philadelphia, 1906 aged 56 died Nov 23 1934 of leukemia and secondary anemia

William David Sloan, Stockton Ga University of Georgia Medical Department, Augusta, 1910, served during the World War, aged 55, died, January 10, in a hospital at Atlanta, of chronic nephritis and heart disease

John Gibson Davis Jr. & Christinburg, Va, Medical College of Virginia, Richmond, 1923, in associate surgeon to the New Altamont Hospital, aged 35, died, January 28, of influenza and gastric hemorrhage

Vertner Kenerson, Eden, N Y Yale University School of Medicine, New Haven, Conn, 1895, veteran of the Spanish-American War, aged 68, died, February 2, of arteriosclerosis, hemiplegia and diabetes mellitus

David Edwin Sloan, Charleroi, Pa Western Pennsylvania Medical College Pittsburgh, 1893, on the staff of the Charleroi Monessen Hospital, Lock No 4, aged 70, died, January 8, of myocarditis and arteriosclerosis

Frederick Lewis Singrey, Mount Vernon, Ohio Starling Medical College, Columbus, 1898, member of the Ohio State Medical Association, formerly county coroner, aged 58, died, January 28, of heart disease.

Marius John Pace, Brooklyn, University and Bellevue Hospital Medical College, New York 1933 aged 28, intern at the Newark (N J) City Hospital, where he died, Dec 23, 1934, of carcinoma of the lung

Douglas Wyatt, New Florence Mo Kansas City Medical College, 1904, served during the World War, aged 57, died, January 11, in the Veterans' Administration Facility, Jefferson Barracks, of pneumonia

George Almon Kelley & Canton, Ohio Homeopathic Hospital College Cleveland 1880, on the staff of the Aultman Hospital, aged 77, died, January 31, of chronic myocarditis and cerebral hemorrhage

Eugene J Gregg, Cleveland, McHarrj Medical College, Nashville 1905, formerly member of the city council aged 53, died, January 4, in the Lakeside Hospital, of empyema and lymphosarcoma

John Louis Hennemuth, Modesto, Calif, University of Minnesota College of Medicine and Surgery, Minneapolis, 1890, member of the California Medical Association, aged 66, died, Dec 9, 1934

Edward Aloysius Tracy, Boston, Harvard University Medical School Boston, 1891, member of the Massachusetts Medical Society, aged 70, died January 12, of carcinoma of the liver

R Watson Graham, Los Angeles, McGill University Faculty of Medicine, Montreal, Que., Canada 1904 fellow of the American College of Surgeons, aged 58, died, Dec 30, 1934

John Harding-Mason & San Francisco, California Medical College San Francisco 1900, aged 72, died, Dec. 13 1934, in St. Francis Hospital, of arteriosclerosis and diabetes mellitus

Edward Everett Pease, Nichols, N Y, University of Michigan Department of Medicine and Surgery, Ann Arbor 1873, died, Dec. 21, 1934, of an intestinal malignant condition

Victor Emmanuel Campbell, Fresno, Calif University of Colorado School of Medicine, Denver 1930, member of the California Medical Association, aged 32, died Nov 28, 1934

John Thorne Nicholson, Bath, N C College of Physicians and Surgeons Baltimore, 1885, aged 76, died, January 31, in the Riverview Hospital, Washington of angina pectoris

Zachary T Gabbert, Casey Creek Ky, University of Louisville School of Medicine, 1881 aged 85, died, Dec 22, 1934, of gangrene of the left foot and bronchopneumonia.

Arthur Clarkson Smith, Oakland Calif, Oakland College of Medicine and Surgery, 1907, member of the California Medical Association, aged 52, died Nov 25 1934

Esther Concordia Johnson, Molme, Ill University of Illinois College of Medicine, Chicago 1931, also a medical missionary, aged 35, died, January 22, of malaria

Eisuke Ishikawa, Stockton, Calif, Tokyo Charity Hospital Medical College, Tokyo, Japan, 1907 member of the California Medical Association, aged 51, died, Nov 28, 1934

Bernard Conried Zall & Philadelphia Medico-Chirurgical College of Philadelphia, 1909, aged 54, died Dec. 22, 1934, in the Mount Sinai Hospital, of angina pectoris

Wilbur LaVerne Sprong, Montreal, Que., Canada Johns Hopkins University School of Medicine Baltimore, 1930, aged 31, died, Nov 23, 1934, in Los Angeles

Trafford Brasee Salisbury, New York, Columbia University College of Physicians and Surgeons, New York 1896, aged 60, died January 12, of pneumonia

William Tilden Smith, Norfolk, Va, Medical College of Virginia, Richmond, 1904, member of the Medical Society of Virginia, aged 57, died, Dec 28, 1934

Leon Gilbert Verrill, Weeks Mills, Maine Dartmouth Medical School, Hanover, N H, 1896, aged 67, died, recently, of edema of the lungs and appendicitis

Francis Fletcher Joyner, Roxbury, Mass, University of Vermont College of Medicine, Burlington, 1900, aged 59, died, January 12, of bronchopneumonia

James Michael O'Brien & Oregon, Wis Rush Medical College, Chicago, 1890, aged 71, died, January 20, in St Mary's Hospital, Madison, of pneumonia

Samuel Richard Arthur Jr & Sacramento, Calif, University of California Medical School, San Francisco, 1931, aged 29, died, Nov 25 1934

William Forest Young, Statesville, Tenn, University of Tennessee Medical Department, Nashville, 1889, aged 72, died, January 27 of pneumonia

Edward Gustav Grahn, Indianapolis Medical College of Indiana Indianapolis 1884, aged 85, died, recently, of arteriosclerosis and myocarditis

David William Vaux & Pittsburgh, Western Pennsylvania Medical College Pittsburgh, 1905, aged 63, died, January 29, of cardiorenal disease

Eugene Gaspard Courteau, St Jacques, Que, Canada, School of Medicine and Surgery of Montreal, 1894, aged 66, died, Dec 28, 1934

John Alexander L McAlpine, Vancouver, B C, Canada, Marion-Sims College of Medicine, St Louis, 1898, aged 67, died, Dec 6, 1934

Joseph Bedford Smart, Marble, N C, Chattanooga (Tenn) Medical College, 1900, aged 63, died, Dec 22, 1934, of bronchopneumonia

Enrique M Aldana, San Francisco, Universidad Nacional Facultad de Medicina, Mexico, D F, 1899, aged 61, died Nov 28, 1934

Howard Felix Adler & San Francisco Harvard University Medical School, Boston, 1908, aged 50, died, January 24, of heart disease.

Carl Forsythe Payne, Franklin, Ind Jefferson Medical College of Philadelphia, 1888, aged 71, died, January 20, of heart disease.

Irwin S Townsend, Detroit, American Eclectic Medical College, Cincinnati, 1879, aged 89, died, Dec 27, 1934, of myocarditis

Alfred S Oliver, St Marys, Ga, Louisville (Ky) Medical College, 1879, aged 77, died, Dec 24, 1934, of hypostatic pneumonia

William David Steen, New York, Columbus (Ohio) Medical College, 1883, aged 73, died, Nov 20 1934, of arteriosclerosis

William Enville Richardson, Los Angeles College of Physicians and Surgeons, Boston, 1910, aged 57, died, Dec. 19, 1934

George Henry French, Long Beach Calif Dartmouth Medical School, Hanover, N H 1886, aged 70, died Nov 28, 1934

Lorenzo Stephenson Webb, Creswell N C University of North Carolina School of Medicine 1905, aged 60, died recently

Eugene Francis Shea, Howard R I Baltimore Medical College, 1894, aged 65, died, Dec 31, 1934 of cerebral hemorrhage

Amanda Maria Congdon, Los Angeles, University of Buffalo School of Medicine 1892, aged 77, died, Dec. 30, 1934

Lester Reginald Weeks, Trenton, Fla, Atlanta College of Physicians and Surgeons, 1908, aged 57, died Dec. 26, 1934

Thomas J Acton, Eubank, Ky, Eclectic Medical Institute, Cincinnati, 1891, aged 70, died, January 23, of pneumonia

Harry Orson Muller, Hemet Calif, Cooper Medical College, San Francisco, 1893, aged 62, died, Dec 3, 1934

Will C Strother, Bowling Green, Ky, Louisville Medical College, 1897, aged 64, died, January 29, of heart disease

Llewellyn James Williams, Los Angeles, Louisville (Ky) Medical College, 1906, aged 55, died, Nov 14, 1934

Hugh O Morgan, White, S D, Fort Wayne (Ind) College of Medicine, 1894, aged 66, died, January 2

Frank Stacy Hawley, Los Angeles, Rush Medical College, Chicago, 1904, aged 62, died Nov 5 1934

Bureau of Investigation

ANOTHER QUESTIONNAIRE

Expert Testimony Required, Price Six Bottles of Beer

Repeatedly has this department of THE JOURNAL discussed the plague of questionnaires that is visited on the medical profession. In its essentials the questionnaire nuisance, as it afflicts the physician, is usually a letter written, occasionally openly and frankly on the stationery of some advertising agency but more often written on the stationery of an organization that exists only on paper and described as some sort of 'Research Bureau'. Such bureaus are in reality merely names adopted by advertising agents or advertising agencies for the purpose of impressing the physician in their attempt to get expert testimony at no cost.

The entire scheme is an outgrowth of the deplorable tendency on the part of advertisers of all kinds of merchandise nowadays to adopt the old 'patent medicine' angle in advertising their wares. 'The medical profession says —,' 'Science declares —,' 'Physicians are of the opinion —,' Such are the leads used by the sellers of soap, of toilet papers, of food products of household utilities and what not in the great game of breaking down sales resistance on the part of the ultimate consumer and the ballyhooing of the products.

The first of what seems likely to be another flood of questionnaires has just been sent in by a California physician. It is a three-page affair. The first page bears the letterhead 'Lord & Thomas, Advertising 235 Montgomery Street, San Francisco', it is signed 'M. Campbell, Director, Division of Research, Lord & Thomas'. The letter itself apparently mimeographed and, as usual, addressed 'Dear Doctor' opens thus:

As between hard liquor and beer for regular consumption very probably you would advise your patients as a whole to drink beer and you would have certain reasons for this.

Will you do us a favor? We think you will be repaid for your courtesy in the suggestions that we expect to make to millions of people urging that they see their physicians with regard to the drinking of beer in connection with such troubles as indigestion, nervousness, sleeplessness, etc.

Then follows another paragraph in which Lord & Thomas state that they believe that they are 'going to do a great deal of good along the lines of *temperance* in an advertising campaign for a client'. The client apparently is somebody who sells beer, and Lord & Thomas ask the physician to make a check-mark opposite a "yes" or a "no" which will only take the physician a moment and will be a contribution 'to the cause of better public enlightenment'.

The two pages that accompany the descriptive letter are mimeographed sheets in which questions are asked and after which "Yes" and "No" squares are placed for the physician to mark with a cross if he is so inclined. There is however considerable space left after each question for 'Additional comment, if any'. The questionnaire proper is prefaced with this paragraph:

Assuming that people are fairly normal in health and that the indispositions referred to are not chronic ailments requiring the immediate attention of a physician, would you say that the following statements are fair assertions of the qualifications of beer as a beneficial beverage?

After stating that the company would not use the physician's name in connection with any publicity without his consent, there then follows the general heading 'STATEMENTS FOR YOUR AGREEMENT, IF YOU ARE IN AGREEMENT' under which are to be found the following categorical statements and questions to which the physician is expected to answer 'Yes' or "No":

1 Beer with meals aids digestion due to its moderate and well balanced content of alcohol.

2 Beer is soothing to the nerves due to the mildly sedative properties of the hops used in the brewing process.

3 Beer taken before retiring at night tends to induce sleep or to aid people in getting to sleep due to the nourishment it puts into the stomach and its mildly relaxing effect.

4 Beer in many cases acts as a mild general tonic tending towards raising the body tone of people who although not actually ill may be said to be under par.

5 The mere additional consumption of liquid by the body that the drinking of beer represents is beneficial to the general body tone and the skin because it tends to flush the system of impurities.

6 Have you ever prescribed beer in connection with the following disorders: Digestive, Nervous, Sleeplessness, Run Down Condition, Need of Tonic, Underweight, Insufficient Liquid Intake, Convalescence, Nursing Mothers?

7 Is beer fattening and under what conditions?

8 Is beer non fattening and under what conditions?

9 Do you regard the general drinking of beer instead of hard liquors as promotion of a beneficial temperance?

These are the statements and questions after which the doctor is asked to place either "Yes" or "No" and write any additional comments that he may care to make. At the end of the questionnaire is a space for the doctor's name and address. A business reply envelop requiring no postage is enclosed.

Most of the questionnaires that physicians receive are, as has already been stated, sent out under false representations as coming from some imposingly named but non-existent research bureau. Furthermore, the only thing the physician is usually offered for his expert testimony is thanks, although there have been some exceptions to this. One may recall the questionnaire that was sent out by Lord & Thomas and Logan of New York in 1927, when physicians were asked to give their expert opinion on the question of whether or not the 'toasting process' applied to tobacco was likely to free the cigaret from irritation to the throat. Lord & Thomas and Logan in that case wrote frankly on the company's stationery and stated at the outset that the physician to whom the question was addressed was being sent a carton of 100 Lucky Strike cigarettes from the American Tobacco Company, the agency's client!

In the present instance Lord & Thomas of San Francisco state at the end of their questionnaire that if the physician would sign his name and address they would have sent to his office or his home a half-dozen bottles of beer (which we hope you will accept with our compliments)."

The sequel to the questionnaire on Lucky Strikes was that the exploiters of that particular brand of cigarets claimed that over 18,000 physicians answered the question in the affirmative—although it was obviously a question that not one physician in a thousand had the technical knowledge on which a scientific opinion could be predicated.

One wonders just how many physicians will consider six bottles of beer (retail value, presumably, about 90 cents) a recompense for specialized knowledge asked by Lord & Thomas.

The questionnaire nuisance will persist as long as physicians play the part of easy marks. Can one imagine for a moment any advertising agency trying to get free legal advice by the questionnaire method? One cannot in this connection do better than call to mind an incident already brought to the attention of the readers of this department of THE JOURNAL in the case of another questionnaire. In May 1926, Lord & Thomas—this time of Los Angeles—sent letters to dermatologists stating that in the interests of their client, the California Fruit Growers Exchange they were 'making a special investigation of the effect of lemon juice when used as a hair rinse' and would be grateful if the physician would answer the questions that Lord & Thomas were sending. There were nine such questions each technical and calling for special knowledge. A well known eastern dermatologist who received one of these pieces of circularization instead of returning the questionnaire, wrote to the agency as follows:

If your client desires to investigate the effect of lemon juice as a hair rinse I have no doubt that you can employ reputable experimenters to make such an investigation. Your request for filling out of questionnaire and obtaining of information gratuitously from physicians I consider an excellent example of colossal nerve and impertinence.

We believe this physician's attitude was 100 per cent sound. The questionnaire nuisance can be abolished overnight if the medical profession will refuse to play into the hands of advertising agencies and would consign all questionnaires from such sources to the wastebasket.

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address, but these will be omitted, on request.

TREATMENT OF ASTHMA

To the Editor—I have a patient aged 29 the wife of a dentist who has been having severe attacks of asthma for some time. All tests have been essentially negative and medication does not give much relief except temporarily. She cannot stand a high altitude and when she is in this city, which has an elevation of 1010 feet, the attacks are daily and in the last week have been constant. Change of climate even for short distances seems to help. Will you be kind enough to give me some suggestions for this condition which I believe to be one of true bronchial asthma and also what climate and elevation would be desirable. Please omit name.

M.D. West Virginia

ANSWER—In answering this query it is to be assumed first of all that the diagnosis is correct and, secondly, that the skin tests have been carefully and completely carried out. Wheezing and dyspnea occur in other conditions besides bronchial asthma.

The diagnosis should be supported by a history of attacks by a history of allergy in other members of the family, by other allergic conditions in the patient herself e.g. urticaria or hay fever, by an eosinophilia in the blood and sputum and by a favorable response to injections of epinephrine. The tests should be carried out as thoroughly as possible and should be done by one trained in this type of work, not by an ordinary laboratory technician with no clinical experience. If anything is uncovered by these tests, elimination of the offending substance is the best method of treatment.

Granting that the diagnostic procedures have been carried out and have failed to disclose the cause of attacks one is forced to fall back on nonspecific treatment which while helpful, does not as a rule yield such good results as specific treatment. Climate itself helps in a few cases, but as there is no one climate suitable for all asthmatic persons it is necessary to try various places. Tucson, El Paso and similar climates seem to help some patients. On the whole warmth helps most asthmatic patients unless the asthma happens to be due to pollens. A simple procedure is to sew in the pillows and mattress with a light rubber sheeting, this helps those sensitive to feathers and house dust, the rubber covering should be washed once a week. Removal of any animals such as cats or dogs should be insisted on no matter what the tests show. The face powder should be changed to a nonallergic brand.

Some cases are aided by removal of from 5 to 10 cc of blood and injection of this quickly intramuscularly (autohemotherapy) some seem to be helped by intramuscular injections of a foreign protein as boiled milk. Other nonspecific measures are also available, if these fail. If the asthma is due to some inhalant, a week or two in a hospital room equipped with an air filter and with rubber-covered mattress and pillows should clear up the condition, temporarily at least.

For the attacks, epinephrine hypodermically and ephedrine by mouth are best, opiates should be avoided as much as possible.

TREATMENT OF SYPHILIS

To the Editor—At the age of 19 a man developed a chancre of the lower lip and gave a positive Wassermann reaction. He was given ten injections of neoarsphenamine and twenty injections intramuscularly of compounds of the heavy metals, bismuth and arsenic. The Wassermann reaction after a rest period was plus minus in the alcoholic antigen and negative in the cholesterinized antigen. A second course was given in which only four neoarsphenamine injections were given, plus twenty of a bismuth compound. Then again following a rest period, a Wassermann reaction of the blood was negative. The man is now 29 years of age eleven years having elapsed since the primary chancre occurred. He has had periodic semiannual Wassermann examinations which have all been negative. About a year ago a spinal puncture was done which came back negative. Now this man is a social service worker and happened to hear Dr. Stokes give a lecture on syphilis last week. Dr. Stokes contention at that time was that all early cases such as he had, should receive at least thirty to forty injections of neoarsphenamine and many more injections of a bismuth compound than he had received. The man is quite concerned about the question as to whether he had adequate treatment at that time and has asked me to advise him accordingly. At the present time he shows no signs or symptoms of syphilis. Blood Wassermann and Kahn tests were both negative. Would you advise him to have any further treatment or merely tell him to go about his business and that he is cured as far as can be humanly told? Kindly omit name and address.

M.D. New York

ANSWER—In considering a situation of this sort, it is necessary to take into account the fact that much or little treatment may, under unknown favoring circumstances, produce

a "cure" of syphilis. In fact, spontaneous cure is well supported by such evidence as that of the Bruusgaard series. From the standpoint of a standardized system of treatment for early syphilis, there can be no doubt that the management of the case was inadequate from the standpoint of the amount of treatment, the introduction of rest periods, the presence of weak or doubtful positives and the use of the Wassermann test as an indication for cessation and resumption of treatment. It is against all these undesirable practices that the recently published standardization has been directed. The situation so far as this man is concerned, however, is that the disease is probably arrested but that he must remain under lifelong observation. Particular attention in situations of this sort should be paid to the cardiovascular mechanism and the patient should at once receive a complete heart study, including teleroentgenogram study of the physical signs, visualization of the aorta with the fluoroscope, and electrocardiograms. Under no circumstances should he be told 'to go about his business, that he is cured so far as can be humanly told.' Lifelong observation in view of the still existing uncertainties regarding the complete curability of the disease is not an unreasonable requirement and if tactfully presented to the patient assumes the guise of a health measure and need not give rise to phobias.

CEREBRAL HEMORRHAGE—AMYL NITRITE TEST—SILENT AREAS—QUININE SALICYLATE

To the Editor—1. In either a cerebral hemorrhage or a thrombosis is the improvement of the ensuing symptoms brought about by the absorption of the clot or by the collateral circulation? Are there any methods or signs whereby the extent of cerebral arteriosclerosis can be determined? 2. Of how much value is the amyl nitrite test of Steiglitz? 3. Can a patient suffer a cerebral hemorrhage of the so-called silent places without pronounced symptoms? 4. Does quinine salicylate raise blood pressure in ordinary doses? Kindly omit name.

M.D. Illinois

ANSWER—1. The gradual improvement that follows the acute and profound symptoms of cerebral accident is due primarily neither to absorption of the clot nor to the development of a collateral circulation but should be attributed to the subsidence of the generalized cerebral edema, which is subsequent to either cerebral hemorrhage or thrombosis. The coma of apoplexy is probably largely a result of increased intracranial pressure from edema of the brain. With the subsidence of this edema the cerebral vessels are less compressed and the general asphyxia of the brain is relieved. The areas actually destroyed by pressure or infiltration of the hemorrhage and by the profound histonoxia are irrevocably destroyed. This destruction is responsible for the persistence of the permanent neurologic symptoms. When only small areas are involved, and especially the cortex rather than the deep tracts the permanent evidences of nerve tissue destruction may be most inconspicuous. Acute angiospasm, if sufficiently brief so that no necrosis results may cause symptoms closely simulating apoplexy but without permanent signs of destruction of nervous tissue.

Clinical determination of cerebral arteriosclerosis (scarring of the intima of the larger vessels) is almost impossible. Arteriosclerosis frequently exists with no demonstrable impairment of the circulation until sudden thrombosis and/or hemorrhage precipitates the critical picture of apoplexy. Indirect evidence of arteriosclerosis of the aorta or main arterial trunks is presumptive of some cerebral involvement. On the other hand, arteriosclerosis of the smaller arteries and arterioles, due primarily to changes in the media, may be estimated with a fair degree of accuracy. Arteriosclerosis is a consequence of hypertensive arterial disease and therefore invariably associated with hypertension. The progressive degeneration in the arterioles probably is the result of the arteriolar spasticity which is likewise responsible for the hypertension. The rate of progression of these degenerative changes is not uniform but varies greatly both in different individuals and in different areas of the body. Therefore the duration of the hypertensive disease is a totally inadequate guide to the extent of sclerosis. Neither is the height of the blood pressure an effective criterion.

2. The amyl nitrite test of Steiglitz has proved to be of great usefulness in estimating the average extent of arteriosclerosis for the body as a whole. Sclerotic vessels are not relaxable by amyl nitrite, whereas spastic arterioles are temporarily relaxed. The test does not and cannot be expected to yield information regarding the condition of the arterioles of specific areas. A marked reduction of the diastolic tension on inhalation of amyl nitrite indicates that there is little or no sclerosis and therefore is presumptive evidence of fairly normal cerebral vessels. On the other hand, a failure of the diastolic tension to fall notably is strong evidence of generalized arteriosclerosis in which the cerebral vessels are probably also involved. Cerebral sclerosis may be somewhat more or less

marked than the test indicates, but it gives one most useful information regarding the condition of the arterioles as a whole. Ophthalmoscopic inspection of the retinal arteries is the most direct method of evaluation of the condition of the cerebral vessels. Cerebral and retinal arteriosclerosis usually, although not invariably, are approximately parallel in degree. As the retina is truly an extension of the brain, this is not surprising. With an extensive drop in the diastolic tension on inhalation of amyl nitrite and nearly normal retinal arteries as observed on ophthalmoscopic examination, one may justifiably conclude that cerebral arteriosclerosis is absent or but minor. The converse, of course, is also true.

3 Very minute cerebral hemorrhages into the so-called silent areas could occur without pronounced symptoms. Involvement of anything but the smallest branches of the arteries however, would cause generalized symptoms at the time of the accident because of the increased intracranial pressure due to edema. After subsidence of the acute phenomena, no permanent injury may be detectable. It is quite probable that many of the acute and transient attacks of aphasia, hemiparesis and monoplegia are due to arterial spasm or vascular crises (Reisman) rather than to hemorrhage or thrombosis.

4 Ordinary doses of quinine salicylate do not raise the arterial tension. In individuals abnormally sensitive to either salicylates or quinine, even small doses may upset the equilibrium of the vasomotor tone.

FUNGI IN SHOES

To the Editor—An intelligent and observant patient has noticed that after he has worn a pair of new shoes for a month or so a green fungoid growth appears inside the shoe near the toe. This is accompanied by a marked odor. He is clean washing daily changing his socks every morning and alternating between two sets of shoes. This fungus does not occur in all shoes and is more noticeable in warm weather. In cold weather the fungus disappears and the disagreeable odor vanishes. He is not suffering with epidermophytosis or any other skin lesion of his feet that could possibly be transmitted to the shoes. He is anxious to know what to do to destroy the fungus and what deodorant is recommended since the ordinary remedies and disinfectants are useless besides the expense of having to discard comparatively new shoes. Please omit name.

M D New York

ANSWER—The infecting fungus is introduced into the shoe by the sock. The patient probably wears silk socks, which, though washed, are not boiled and so retain the infection or, if they are boiled, become reinfected in some way. Silk can be sterilized by soaking it for twelve hours in a 1:1,000 solution of corrosive mercuric chloride before washing.

After as much as possible of the fungus has been wiped out of the shoe, it should then be sponged inside with strong formaldehyde solution, care being taken not to get it on the hands. Then a piece of cotton or blotting paper saturated with formaldehyde should be left in the toe of the shoe and the shoe should be wrapped securely in paper. After twenty-four hours the cotton or blotter should be removed and the shoe aired thoroughly before it is again worn. Fungi are very difficult to remove from leather, and repeated treatments may be necessary.

ASTHMA AND CONTINUED USE OF EPINEPHRINE

To the Editor—A man who for many years has been troubled with hay fever and an associated asthma has been in the habit of purchasing epinephrine at the drug store and administering it hypodermically for relief from attacks. Over a period of several years he has steadily developed a tolerance for the drug and consequently has had to increase it from time to time in dosage. When I first saw him he came in complaining of dizziness and extreme weakness of the asthmatic type. The most pertinent finding in the examination was a blood pressure reading of 88 systolic 60 diastolic. Second to this was the hemoglobin 58 in Sahli units. He also had several abscessed teeth. What I should like to know is whether or not the taking of epinephrine in large doses has had any thing to do with the hypotension. Since the systolic pressure is high enough to give a pulse pressure of 28 mm of mercury it would seem to be primarily a vascular weakness and not so much myocardial. There are no evidences aside from that mentioned of Addison's disease. The man is 42 years old. The anemia is of the hypochromic type. Please omit name.

M D Minnesota

ANSWER—Many patients with chronic asthma have been forced to use epinephrine for long periods. It is the unanimous opinion of all specialists in this field that the continued use of epinephrine does not tend to cause habit formation. It is likewise agreed that the continued use of epinephrine has no effect whatever on the blood pressure, it neither increases it nor decreases it (von Gordon, L. *Schweiz med Wchschr* 54:330 [April 3] 352 [April 10] 1924; Pagniez, P., and Escalier, A. *Bull Soc méd d hop de Paris* 50:619 [April 23] 1926 abstr. *THE JOURNAL*, June 19 1926, p. 1948). As

a matter of fact, if a patient has a hypertension and also has an attack of bronchial asthma epinephrine is given as if the hypertension did not exist. The blood pressure usually falls after the attack is over.

In this case the hypotension and the anemia may have little to do with the bronchial asthma. The dizziness described probably results from the continued use of epinephrine and along with this one often finds pallor, tachycardia, palpitation and blurring of vision. These symptoms all cease when the epinephrine is withdrawn.

If they have not already been done, a complete examination and skin tests should be made to try to find the cause of the asthma.

PHLEBITIS

To the Editor—A woman aged 45 has a network of superficial varicosities in both legs and extending above both knees. Each time she has to be in bed for a few days she develops thrombosis and she has been advised by good men never to be operated on. When she is up however and wears good elastic stockings, she has very little trouble. Routine tests for deep venous involvements are positive. In fact a few years ago a physician attempted the injection method of treatment but had to discontinue it on account of ill results. It seems that an operation (gallbladder) is inevitable for this woman and I should like to know the best precaution to take against thrombosis and phlebitis. I might add that the patient has no cardiorenal involvement. Please omit name.

M D Texas

ANSWER—In patients of the type described, a thorough search for sources of infection should be made, the teeth, tonsils and low grade pelvic infection are the chief foci. Nothing is mentioned about the onset of these varicosities, but if there is a deep venous obstruction it probably originated from a pelvic thrombosis following childbirth, operation or some infectious disease. The activity of the phlebitis can be gaged by the determination of the sedimentation time. There is no absolute safeguard against postoperative phlebitis, but the following measures seem to diminish its incidence: 1 A fluid intake of 3,000 cc. before and the first two weeks after the operation. 2 The maintenance of normal blood pressure and circulation with the help of caffeine and ephedrine after the operation. 3 A Trendelenburg position of 30 degrees after the operation which should be maintained so long as the patient is immobilized. 4 Early respiratory and muscular exercises and early mobilization of the patient.

OPERATION ON FISSURE OF LIP

To the Editor—I would like information as to the best method of operating on a central fissure of the lower lip. The lesion has been treated in every conceivable manner over a period of several years by several different physicians and is steadily becoming worse. A small amount of granulation-like tissue on either side of the fissure covering an area about the size of a flat surface of a split pea proved at biopsy to be benign and apparently is tissue reaction to the chronic inflammation resulting about the region of the fissure. The patient is a white man aged 35. Kindly omit name.

M D California

ANSWER—The preferable method of treating such a persistent fissure of the lip is to excise it including a V extending down on the lower lip some distance below the red margin. This will permit a good plastic closure with no puckering and no noticeable deformity if the red margins are carefully approximated and the edges sutured accurately with fine silk. The slightly narrower lower lip will be scarcely noticeable after a few months.

LAVENDER COLORATION OF GRAY HAIR

To the Editor—A woman aged 42 has been under treatment for four years for hypertension and coronary sclerosis. Twice during this period her hair naturally gray has assumed a lavender tint. No applications have been made and she has not changed her shampooing materials. Her medication has been largely barbiturates and other sedatives though she has recently taken dinitrophenol. Can you suggest any reason for this peculiar discoloration of the hair?

EDWARD F. MALLOY, M.D., Stamford Conn.

ANSWER—Isn't the patient using bluing in her rinsing water after the shampoo? If so she should cease the use of it. Any such change of color must be from an external cause. It may be that on these occasions the bluing was used too lavishly.

THYROID EXTRACT AND BLOOD SUGAR

To the Editor—Will thyroid extract in suitable doses have a tendency to raise the blood sugar in an obese elderly white woman with diabetes?

N. L. MISTACHIN, M.D., St. Louis

ANSWER—Yes

Council on Medical Education and Hospitals

ABSTRACT OF MINUTES OF THE COUNCIL BUSINESS MEETING HELD AT CHICAGO, FEB 17, 1935

1 In September 1933 the Council on Medical Education and Hospitals recognized the necessity of a restudy of medical education and decided on a reinspection and reclassification of the medical schools of the country. In February 1934 a special appropriation was voted by the Board of Trustees of the American Medical Association and in September of that year Dr Herman G Weiskotten began the personal inspection of some of the schools. It is the policy of the Council to employ two inspectors in each visit in order to eliminate as far as possible the personal equation and to secure well balanced and dependable reports. In addition to the class A medical schools of the United States, Canadian schools have voluntarily requested that they be included in this study. The Council has also determined to include in the survey the unrecognized medical schools. To date, twenty-eight schools have been visited.

2 During the year 1934, inspections of hospitals and technician schools were made as follows

(a) Hospitals

Tuberculosis sanatoriums	230
Intern hospitals	157
Residency hospitals	30
Small hospitals	152
Other registered hospitals	23
Total	592*

* Twenty of these hospitals are maintained exclusively for Negroes

(b) Schools for Technicians

Schools of laboratory technic	85
Schools of physical therapy	23
Schools of occupational therapy	6

Total **114**

Total number of inspections **706**

3 It was resolved that the approval of a medical school be withdrawn at the first meeting of the Council if on inspection it is found that it does not and cannot possibly meet the standards of the Council.

4 It was resolved that at the close of the current academic year the Council should review all inspections that have been made and take appropriate action.

5 It was resolved that a communication be sent officers of medical schools calling attention to the following paragraph from the Essentials of an Acceptable Medical School:

The number of students to whom an adequate medical education can be given by a college is related approximately to the laboratory and hospital facilities available and to the size and qualifications of the teaching staff. A close personal contact between students and members of the teaching staff results in an efficiency which is not possible in an institution where the number of students is excessive.

Although only about one third of the schools have been visited, it is already apparent that this requirement of the Essentials is not being generally met and that a large proportion of the schools are accepting larger numbers of students than they can properly teach.

6 The Council's survey of medical education was discussed at a luncheon with the executive council of the Association of American Medical Colleges and it was suggested that a survey of postgraduate medical education should be undertaken. The Council requested that this suggestion be placed on record to be considered at a later date.

7 It was resolved that the proposed Essentials of an Approved School of Occupational Therapy be approved.

8 It was resolved that section A, No 3, of the Essentials for Examining Boards in Specialties, be changed to include the words italicized as follows:

Membership in the American Medical Association or by courtesy, membership in such Canadian or other medical societies as are recognized for

this purpose by the Council on Medical Education and Hospitals of the American Medical Association. Except as here provided membership in other societies should not be required.

9 It was resolved that section III, C, No 3, of the Essentials for Examining Boards in Specialties, be amended to include the words italicized as follows:

An additional period of not less than two years of study and/or practice

10 It was resolved that special boards applying for approval should file copies of their official records with the Council as well as with the Advisory Board for Medical Specialties.

11 It was resolved that, if competent, a physician might be certified by more than one special examining board.

WILLIAM D CUTTER, M D, Secretary

ADDITIONAL HOSPITALS APPROVED

The Council on Medical Education and Hospitals of the American Medical Association has given its approval to the following hospitals since the publication of the last previous list in THE JOURNAL, Nov 10, 1934.

Hospitals Approved for Intern Training

ARMY HOSPITALS

Letterman General Hospital San Francisco
Fitzsimons General Hospital Denver
Walter Reed General Hospital Washington D C
William Beaumont General Hospital El Paso Texas
Station Hospital Fort Sam Houston San Antonio Texas

PUBLIC HEALTH SERVICE HOSPITALS

U S Marine Hospital San Francisco
U S Marine Hospital Chicago
U S Marine Hospital New Orleans
U S Marine Hospital Baltimore
U S Marine Hospital Ellis Island New York City
U S Marine Hospital Staten Island N Y
U S Marine Hospital Norfolk Va
U S Marine Hospital Seattle

Evangelical Hospital Chicago
St Joseph's Hospital Joliet Ill
Wichita Hospital Wichita Kan
Evangelical Deaconess Hospital Detroit
Burlington County Hospital Mount Holly, N J
St Joseph Hospital, Paterson N J
Bushwick Hospital Brooklyn
Kingston Hospital Kingston N Y
Misericordia Hospital New York City
Trinity Hospital Minot N D
Knoxville General Hospital Knoxville Tenn
St Mary's Hospital Milwaukee

Hospitals Approved for Residencies in Specialties

Compton Sanitarium Compton Calif Psychiatry
Central Dispensary and Emergency Hospital Washington D C
Medicine and surgery
Freedmen's Hospital Washington D C Medicine surgery pediatrics
gynecology and obstetrics
Western Maine Sanatorium Greenwood Mountain Me Tuberculosis
Rutland State Sanatorium Rutland Mass Tuberculosis
Sbriners Hospital for Crippled Children Springfield Mass
Orthopedics
Middlesex County Sanatorium Waltham Mass Tuberculosis
Dr William J Seymour Hospital, Eloise Mich Medicine, surgery
urology, ophthalmology and otolaryngology
Wheatley Provident Hospital, Kansas City Mo Pediatrics
Atlantic City Hospital, Atlantic City N J Mixed
New Jersey State Hospital Greystone Park, N J Psychiatry
Burlington County Hospital, Mount Holly N J Surgery
Bender Hygienic Laboratory Albany N Y Pathology
Norwegian Lutheran Deaconesses Home and Hospital, Brooklyn
Medicine surgery pediatrics and obstetrics
U S Marine Hospital Ellis Island New York City Psychiatry
St Anthony's Hospital Oklahoma City Okla Surgery and mixed
Eagleville Sanatorium for Consumptives Eagleville Pa Tuberculosis
Roper Hospital Charleston S C Medicine and surgery
Medical Arts Hospital, Dallas Texas Mixed

Hospitals Approved for Additional Residencies

Indianapolis City Hospital Indianapolis Urology and psychiatry
Kings County Hospital Brooklyn Tuberculosis orthopedics neuro-
surgery plastic surgery radiology pathology and dermatology
syphilology
City Hospital, Cleveland Radiology and urology

Minnesota October Report

Dr E J Engberg, secretary, Minnesota State Board of Medical Examiners, reports the oral, written and practical examination held in Minneapolis, Oct 16 18, 1934. The examination covered 12 subjects and included 60 written questions. An average of 75 per cent was required to pass. Sixty candidates were examined, all of whom passed. One physician was licensed by reciprocity and 1 physician was licensed by endorsement. The following schools were represented:

School	PASSED	Year	Per Cent
University of California Medical School	(1934)	92.5	
Emory University School of Medicine	(1932)	93.3	
Northwestern University Medical School	(1932)	90.4

Book Notices

Recent Advances in Neurology By W. Russell Brain M.A. D.M. F.R.C.P. Physician to the London Hospital and J. B. Strauss M.A. D.M. M.R.C.P. Assistant Physician to the Cassel Hospital for Functional Nervous Disorders. Third edition. Cloth. Price \$5. Pp. 442 with 40 illustrations. Philadelphia: P. Blakiston's Son & Company Inc. 1934.

The previous editions of this book have received favorable reviews. As in all books dealing with such highly technical material differences of opinions by reviewers have indicated that there are parts in the present work that might be severely criticized. Probably the criticisms of previous editions were based on the fact that too much physiology and not enough clinical neurology was given. If one compares the past editions with the present one, a marked change for the better can be detected. A number of purely physiologic topics have been left in, but they have a more significant relationship to the clinical information given than did the topics that have been omitted. Between the second and third editions a number of important researches have been reported, and the most important of these are included in the present book. There is much material devoted to encephalomyelitis; also there is a good summary of the observations made during the St. Louis encephalitis epidemic. This book continues to hold its own as one of the best volumes in the 'Recent Advances' series. The multifarious information available to the practitioner in neurology makes it necessary for him and his students to have a volume such as this for quick reference. Neurologists with individual hobbies to ride will continue to differ with the authors' treatment of almost every subject but they will probably be forced to admit that outside of their own particular interest the book will appear to be satisfactory. The authors should be commended for their painstaking work and the amount of improvement they have brought about between the first and latest editions.

Éléments de chimie organique biologique. Introduction chimique à l'étude de la biologie générale. Par Michel Polonovski professeur à la Faculté de médecine et de pharmacie de Lille et Albert Lespagnol agrégé de pharmacie à la Faculté de médecine et de pharmacie de Lille. Préface de A. Desgrez. Paper. Price 100 francs. Pp. 594 with illustrations. Paris: Masson & Cie. 1934.

This is an encyclopedic presentation of the structural relations and properties of organic compounds of biologic importance or interest. The fundamental facts and reactions of elementary organic chemistry are not presented but most of these reactions are applied in developing the evidence for the structural formulas for the numerous substances under consideration. This evidence is given in the usual manner, however, without any emphasis on the quantitative character of the reaction involved. In common with most textbooks in organic chemistry, this volume is inaccurate on the biologic aspects, thus the synthesis of carbohydrates and amino acids in plants, the true nature of hormones and their action and the origin and fate of the organic compounds are treated too simply. Insulin is simply considered as a protein without any suggestion as to the incompleteness of present knowledge of its composition. The testis hormone is stated as having been separated in crystalline form and that its actions were discovered by Brown Seward. Carbohydrates are discussed from the organic point of view. The evidence for the structure of the disaccharides and trisaccharides is presented together with valuable tables covering the physical and chemical properties of the substances. Polysaccharides and heterosides are adequately treated from the chemical point of view, but the statements about enzyme action on carbohydrates are entirely too brief to be accurate. Interesting information on phenols, terpenes and plant pigment is followed by the discussion of lipins. Here is a good presentation on the chemistry of the sterols, but the treatment of fats and phospholipins would have been much improved if a more quantitative point of view had been taken. The amino acids are treated very satisfactorily as such and their structural relations to bases and other products are presented clearly. Relatively little is given on the structure of the proteins. The blood and bile pigments, other porphyrins and chlorophyll are presented quite completely. Many chapters contain short sections covering inadequately qualitative and quantitative methods for some of the substances discussed.

Gynecology By Brooke M. Anspach M.D. Professor of Gynecology Jefferson Medical College. With the assistance of Philip F. Williams M.D. Assistant Professor of Obstetrics School of Medicine University of Pennsylvania and Lewis C. Schoffey M.D. Assistant Professor of Gynecology Jefferson Medical College. Fifth edition. Cloth. Price \$9. Pp. 832 with 679 illustrations. Philadelphia: London & Montreal: J. B. Lippincott Company. 1934.

In this edition of one of the best of American textbooks on diseases of women, many of the chapters have been rewritten entirely, such as those on endometriosis, ovarian tumors and the various menstrual disorders, and all the material in the book has been brought down to date by extensive reediting and resetting. The order of the chapters is traditional but logical, and this, together with easy readability, enhances the value of the book to both student and practitioner. The numerous illustrations are excellent and well selected, although some of them, especially those depicting obsolete procedures such as the Dudley and Pozzi operations on the cervix, might well have been omitted. By all the customary standards, therefore, the book may be warmly recommended. The only question would seem to be as to the size and scope of the volume. It is rather bulky, much larger and more closely set than in the early editions, and this detracts somewhat from its value for the student. There are textbooks that go to the opposite extreme, their brevity and condensation being attractive to the average student but making them less useful for the general practitioner or the gynecologist looking for fuller discussion. The large size of the present work is due chiefly to the inclusion of a good many rather general chapters, with chapters also on diseases of the urinary organs, diseases of the anus and rectum, and diseases of the abdominal viscera associated with pelvic disorders, as well as chapters on such subjects as the relation between nervous and gynecologic disorders and vaccine and serum treatment. Every one knows that the gynecologist, like all other specialists, must know something of other fields, but whether a treatise on one specialty should include a smattering of discussion of allied fields is at least open to question, particularly as every intelligent specialist has at command fuller sources of information on allied subjects. The size of the work could have been cut down materially without lessening its attractiveness to most readers, and with a real increase of its value to the medical student. This one criticism, however, does not alter the fact that the Anspach work is an excellent one and that it fully merits the popularity which it has had for so many years.

Histoire de la chirurgie française (1790-1920) Par J. de Fourmestraux. Préface du Professeur J. L. Faure. Paper. Price 30 francs. Pp. 232. Paris: Masson & Cie. 1934.

No more romantic or thrilling times can be conceived than those occurring in France from 1790 to the end of the Great War in 1920. It is natural that the turbulent days as well as the calm ones should be reflected in the personalities of the men living and working, studying and fighting during this period. It is not surprising, therefore, that a history of French surgery of these times, especially if well written, should abound with interesting characters, characters which like the times were turbulent or calm, passive or aggressive, overly ambitious or surprisingly self-effacing. This history is well written and as a result it reads not like a textbook but like a novel. The history commences while surgery was living under the refulgent light of the Royal Academy, which light was forever dimmed in 1793. The early chapters have to do with the tragic hours of the Revolution—hours through which strong personalities such as Desault, Chopart, Deschamps and Alexis Boyer lived, bowed down or unaffected by the times according to the personalities. The chapter on Dupuytren and his contemporaries is extremely good reading leading up into the equally stimulating events following the description of the first introduction of general anesthesia. It is natural, of course, that the period of Pasteur, Championnière and others involved in the introduction of antiseptics in surgery should be replete with incidents of interest especially to the modern surgeon, because during these periods much of what is in common use today was born. The actual history ends with the chapter on the war, although the final analysis, by the author, of the evolution and the future of surgery is a fitting closure for the work. The French is simple and can be easily read by any one with a moderate working knowledge of the language. The book is to be recommended to any physicians having interest in the history of medicine.

Heredity and Disease By Otto L. Mohr M.D. Professor of Medicine the Royal Frederiks University Oslo. Cloth. Price \$3.50. Pp. 253 with 107 illustrations. New York: W. W. Norton & Company, Inc. 1934.

This volume contains the Edward K. Dunham lectures at the Harvard Medical School in 1933 on Genetics and Pathology. The first half of the book explains in direct, lucid and simple terms the complicated mechanisms of heredity. The second half critically summarizes the major accumulations of data derived from medicine which reveal evidences of the factor of heredity in relation to disease, pathologic susceptibilities and abnormality in man.

Landsteiner's normal blood groups present a typical case of multiple allelomorphism. Falsely alleged paternity lends itself to partial determination by testing the blood group of mother, child and alleged father. In two thirds of such tests no answer in either direction can be given, but in one third of them a particular man might be excluded from the paternity in question, even in this third, however, no particular man can be proved to be the father, since the test merely reveals the blood group to which the father belongs.

Representative cases of hereditary disease and congenital defect are best known in the eye, since this organ is subjected to a great refinement of diagnosis. Thus both dominant and recessive types of microphthalmus are known, one of which is sex-linked. This defect is often associated with cleft iris, cataract, opaque lens or lens luxation. Hereditary degeneration of the macula and retinitis pigmentosa both occur in dominant and recessive sex-linked forms and in 22 per cent of 366 pedigrees were associated with deafness. Optic atrophy is a fatal sex-linked recessive developing after puberty. Moon eye, or congenital night-blindness, is a simple dominant traced for ten generations but recessive sex-linked cases also occur. Red-green blindness in four distinct types is also perfectly sex-linked. Glaucoma is both dominant and recessive sex-linked, cataract mostly dominant and a considerable number of pupils in schools for the blind are genetically blind. In the field of neuropathology (nerve diseases) different hereditary types of progressive muscular, neural or spinal dystrophies, of spastic spinal paralysis and paraplegia, of spinal ataxia (Friedreich's type) and cerebellar ataxia occur, conditions that all involve paralysis or lack of coordination of different parts of the muscular system. Further, Huntington's chorea, 'St. Vitus' dance,' associated with progressive mental disturbances, is typically dominant, while the progressive hepatolenticular degeneration known as Wilson's disease, in which both the liver and one of the so-called basal ganglions of gray matter in the brain are simultaneously affected, is recessive.

Deafness may be induced by different simple recessive genes, otosclerosis by a simple recessive gene, and harelip in varying degrees by a single dominant gene. Diabetes mellitus is inherited as a recessive, but cases of incomplete dominance are also known, while diabetes insipidus is a clear-cut dominant.

From case histories it appeared that various types of protein hypersensitiveness in man were inherited, but recently Ratner has shown that sensitizing antibodies pass through the placenta into the blood of the fetus. A varied body of evidence from plants and animals indicates that immunity may be distinctly hereditary. Examples are constantly multiplying of monofactorial mendelian inheritance of pathologic states in different fields of pathology, including dermatology, otology, orthopedics and dentistry. Mutations paralleling conditions in man are being recorded in laboratory animals though it is not improbable that not a few of these are in reality of genetic origin.

Lethal genes are well known in experimental plants and animals and have been detected in domesticated animals. Ichthyosis congenita in man is due to a lethal gene, xeroderma pigmentosum and infantile amaurotic idiocy to sublethal ones. The primary sex ratio of 150 boys to 100 girls with a selective intra-uterine death rate, which reduces this ratio to 106 to 100 at birth has been inferred to be due to lethal and sublethal sex-linked genes.

There is an extended discussion of disease in fraternal (dizygotic) and identical (monozygotic) twins, the upshot of which is marked support of the hereditary aspect of disease or of susceptibility to it, along with some evidence of the modifying effect of environmental conditions on its incidence. There are also discussions of intersexuality, sex reversal, pseudohermaphroditism, freemartins, genes and hormones, and x-rays and heredity.

While x-rays produce heritable mutation, there appears to be no sound evidence for the belief that alcohol, lead or other chemicals can cause genotypical changes.

The evidence on the inheritance of cancer is as yet quite limited. Malignant pigmented tumor in *Drosophila* has been traced by genetic analysis to single autosomal or sex-linked recessive genes. A certain strain of Arabian horses has a dominant gene for gray coloration and turns gray with age, at which time pigmented spindle cell sarcomas develop around the openings of the body, under the scapula, and in the axillary glands. In the light of cancer investigations, tumor formation seems to be a function of two sets of influences, local irritation and genetic susceptibility. The pathologic history of identical twins supports the idea of a hereditary susceptibility.

Genetics is related to human affairs, but Dr. Mohr is far from supporting the claim of eugenic reformers. His chapter on this theme should be widely read. His conclusions, brief and categorically stated, are that, though not always accepted inbreeding or intermarriage, as such, has no harmful effects at all. Such effects arise only when the genes are bad and tend to be expressed whenever a child gets a double dose from seemingly normal parents each conveying the undesirable gene as a recessive. Inbreeding as such is not the cause of degeneration of families or races. Disappearance of the family name does not eliminate descent of family traits through female lines. Race crossing as a cause of degeneration is deprecated with emphasis because of political use of genetic ideas, especially in Germany. The author has no Nordic illusions, from the standpoint of a pure bred dog we are all curs. He is even more disdainful of "blue blood" and the significance of eminent ancestors, treating this aspect of human heredity with the same fine scorn with which he attacks maternal impressions rationalized human breeding, and sterilization. This attitude is in sharp contrast with his insistence on the hereditary aspects of pathologic states of the human body. There is no reference in these connections to the significance of Galton's studies on human genius. As a matter of fact the doctor seems to be quite like most men when he descends from the relations of heredity to disease to its relations to the fields of social and political action.

Radiologie de la vésicule biliaire. Etude anatomique fonctionnelle et clinique. Par Nemours Auguste, radiologiste de l'Hospice Paul Brousseau. Préface du Professeur Roussay. Paper. Price 45 francs. Pp. 186 with 129 illustrations. Paris: Masson & Cie. 1934.

The clinician, the surgeon and the radiologist all place a different value on the merits of cholecystography. Without making any comparisons, the author of this work has attempted to explain the lack of agreement between the clinician and the radiologist in the diagnosis of diseases of the gallbladder. Less than the usual number of half-tone reproductions of cholecystograms appear in the work, but there are numerous diagrams sketched from x-ray films, which serve well the purposes of illustration. After an excellent historical review of the role of roentgen examinations in gallbladder diagnosis, the author enters into a full description of the radiologic anatomy of the biliary tract, including an interesting study of the extrahepatic biliary ducts and their variations. A lengthy discussion concerns the known functions of the gallbladder in relation to the cholecystographic observations. Technical considerations are fully elaborated, as well as the normal and pathologic aspects of the visualized gallbladder. Final chapters deal with the unusual lesions such as cancer and other tumors of the gallbladder, and the indirect radiologic signs of gallbladder disease.

Aids to Operative Surgery. By Cecil P. G. Wakeley D.Sc. F.R.C.S. F.R.S. Senior Surgeon King's College Hospital London. Second edition. Cloth. Price \$1.25. Pp. 225 with 3 illustrations. London: Baillière Tindall & Cox. Baltimore: William Wood & Co. 1934.

It is more than a decade since the first edition of this little book was written by Mr. H. C. Orrin. During that time many innovations have developed in the field of surgery. The present author has practically rewritten the work, rearranged the chapters in conformity with the accepted chronological order of subject matter presentation, and has added some illustrations. Mr. T. Keith Lyle has assisted in the reconstruction of this valuable 'aid,' which in view of the rapid revision in the practice of surgery will find a useful place in the working library of younger and less experienced surgeons.

Lehrbuch der Differentialdiagnose Innerer Krankheiten Von Professor Dr. M. Matthies. Fortgeführt von Professor Dr. Hans Curschmann. Direktor der medizinischen Universitätsklinik in Rostock. 1. M. Seventh edition. Paper. Price 28 marks. 1 p. 804 with 120 illustrations. Berlin Julius Springer 1934.

This volume, which has established itself as a classic, constitutes one of the best works on differential diagnosis of internal diseases in any language. The book, originally written by Matthies, has been completely revised by Curschmann, who has omitted obsolete and added new material. The discussion is so thorough and complete, including symptomatology in addition to the differential diagnosis in the strict sense of the word, that the book can be considered a real cyclopedia in this field. It is written in a fluent style and the text generously illustrated with numerous temperature charts, schematic drawings, and excellent reproductions of roentgenograms and electrocardiograms. Bibliographic references are confined chiefly to the German literature. The symptoms under discussion are specified in the margin, thus facilitating a rapid survey of the subject. Several omissions have been noticed: tularemia, undulant fever, and the occurrence of a postprandial attack as characteristic for acute pancreatic necrosis. The description of allergic conditions is rather inadequate. A statement that only seventy extracts are available for skin tests is obsolete. All in all, as a reference book this work is unsurpassed, it may be considered as one of the most valuable contributions to the German medical literature in recent years.

Facts and Theories of Psychoanalysis By Ives Hendrick M.D. Cloth. Price \$3. Pp. 308. New York. Alfred A. Knopf 1934.

Although it is probable that psychoanalysis as a technique has come to stay, there still remain many questions about justifying the theories behind it. There are dissensions between members of the analytic and nonanalytic groups of psychiatrists and even some differences of interpretation and opinions among the Freudian psychoanalysts themselves. Nevertheless, when those who have a proper background discuss psychoanalysis, they usually agree on the fundamentals. Much of the dissension has arisen from the lack of a good book on the basic theories and beliefs that are held by properly qualified psychoanalysts. The present volume is a compendium of psychoanalytic theories. There is little in it that is controversial and its facts are largely those presented by Freud himself rather than the products of some of his more bizarre disciples. The first part of the book presents the history of Freudian psychology and the meaning of psychosexuality, the second part treats of the theories of psychoanalysis in which principles such as pleasure and reality are discussed. Aggressive behavior toward parents is included here. Thirdly, there is a clear outline of psychoanalytic therapy, such associated phenomena as transference, also a discussion of treatment methods and the types of patients that are suitable for such treatment. The results of analysis are chiefly set forth, possibly with a little tendency to overvalue some of them. The only part of the volume subject to criticism, and that only mild is the fourth part, in which the author's view seems to be too rosy about the place of psychoanalysis and a little too condemnatory to other schools of psychotherapy. This work should be an excellent basic book for any one who wishes to understand psychoanalysis as it is presented today. It should supersede most of the older books devoted to the presentation of psychoanalysis for the beginner.

Anatomie der Hörrinde als Grundlage des physiologischen und pathologischen Geschehens der Gehörswahrnehmung Von Professor Dr. Max de Crizia. Direktor der Psychiatrischen und Nervenklinik an der Universität Köln. Paper. Price 6.00 marks. Pp. 44 with 22 illustrations. Berlin Julius Springer 1934.

In this excellent and concise monograph the author reviews the fundamental works of Heschl, Wernicke, Flechsig, Brodman, Economo, Cajal and others in conjunction with his own histologic studies in which a special silver impregnation method was used. He charts the various fields described by different authors and presents slides demonstrating variations in architectonic structure peculiar to these fields. With this foundation the author proceeds to a consideration of the physiology of the hearing centers, discussing the conclusions of his predecessors in the light of animal experiments and postmortem observations in cases of trauma, tumor and destruction of the peripheral end organs. The relationship between tone and noise perception, the musical sense and similar topics are considered together with the psychic interpretation and certain analogies drawn between

hearing and vision and the other senses. Stress is laid on the similarity between the Cajal acoustic cells found in the temporal lobe and those of the spiral ganglion. He points out that, when degeneration takes place in the ganglion cells, the Cajal and Korner cells in the brain are found to be the earliest and most markedly involved. As to Hensche's teachings regarding the role of the transverse convolution and its overlying cortical convolutions, the author is not in complete agreement.

Human Values in Psychological Medicine By C. P. Blacker M.C. M.A. M.D. Cloth. Price \$2.50. Pp. 170. New York & London. Oxford University Press 1933.

This volume is an unusual one to find in a medical collection. While its title would indicate that it treats of psychiatric matters, it is necessary to wait until one reaches the last three of the ten chapters before anything distinctly psychiatric is obtained. By use of quotations from philosophic, biologic and psychoanalytic literature, taking matters from miscellaneous sources without a great deal of self criticism, the author has derived a theory which postulates that human capacity and human reactions are largely based on the values which the biologic entity places on life. These values may be distinct from what are called facts yet serve a biologic purpose. They are often esthetic in nature. Case histories and experiments have no place in the presentation, but the author can justify the fact that he applies his theory to psychologic medicine by pointing out that it is the presence of abnormal values which makes the patient seem abnormal. He also links up his theory with Freud's theory of life and death instincts, but he shows that in some respects his attitude toward such fundamental phenomena is different from those of Freud. He apologizes for not having an adequate philosophical background—and this he should do because the book is not a definite application of any clear-cut philosophical doctrine. He also expresses a debt of gratitude to Freud, which seems to have no relation to his theory as he expresses it. The chief value of this book lies in the fact that it may be food for thought for those who can plow through it. As a source or textbook for the busy psychiatric clinician, it would seem to have no value.

Medizinische Praxis. Sammlung für ärztliche Fortbildung. Herausgegeben von Prof. Dr. L. R. Grote, leitender Arzt der medizinischen Klinik des Staatlichen Krankenhauses Zwettkau. Prof. Dr. A. Fromme, Direktor der chirurgischen Abteilung des Stadtkrankenhauses Dresden-Friedrichstadt und Prof. Dr. K. Warnekros, Direktor der staatlichen Frauenklinik zu Dresden. Band XVIII. Eropathologie. Ein Lehrbuch für Ärzte. Von Dr. Otmar Führer, Verzeichner, a. o. Professor der Universität Berlin. Paper. Price 8 marks. Pp. 218 with 32 illustrations. Dresden & Leipzig. Theodor Steinkopf 1934.

This monograph is intended for the instruction of physicians, especially in Germany, in matters relating to the heredity of disease. It deals mainly with the fundamental general principles of heredity, with the influence of heredity especially in human diseases and with the practical application of the knowledge of heredity in medical practice and in public health, with particular reference to the conditions in Germany at the present time.

Early Forerunners of Man. A Morphological Study of the Evolutionary Origin of the Primates. By W. E. Le Gros Clark, D.Sc., F.R.C.S., Professor Elect of Anatomy, University of Oxford. Cloth. Price \$5. Pp. 296 with 89 illustrations. Baltimore. William Wood & Company 1934.

The author has been for many years a careful student of comparative anatomy, especially interested in the nervous system and the skull. The student of comparative anatomy sees spread out before him a picture of progressive evolution. That picture is presented in this book as the author follows evolution from the basal mammalian stock in the Jurassic period up through the higher mammals and the primates to man. In successive chapters he shows parts of the evolutionary picture as presented by skulls, teeth, limbs, brains, special senses, the digestive system and the reproductive system. Of all these the most important part is the brain. Since it is the dominant part of animal structure, the study of its evolution throws the most reliable and significant light on human origins. Professor Clark believes that his study reveals the working of the principle of orthogenesis, early and somewhat intemperately championed by Theodore Eimer, according to which variations are definitely, progressively and irreversibly directed along certain lines. Whitman and others found in their work facts that forced them to accept this principle. The author finds it

"increasingly difficult to conceive of evolution as a matter of action and reaction between the physicochemical factors of the environment and those of a passive organism." The many instances of obvious parallelism in the evolution of primates can be interpreted only by the conception of predetermined trends of development, operating independently of natural selection. "But if the mysteries of the living and evolving germplasm are even deeper and more enigmatical than we have been inclined to believe it were better to recognize the fact." The book is a valuable contribution to the study of evolution and of human origin. Thoughtful biologists and philosophers cannot fail to consider seriously the facts presented.

Medicolegal

Autopsies Liability of Charitable Hospital for Unauthorized Autopsy—The plaintiff's husband died in the defendant hospital, Dec 5 1929, at 8 p m. The body was removed to the hospital morgue. The following morning at 9 o'clock an undertaker procured by the plaintiff, called at the hospital for the body but was told by the hospital authorities that it was not then ready for delivery. He was compelled to wait until 2 o'clock in the afternoon before he obtained the body. It was later discovered that without the consent of the plaintiff an autopsy had been performed on the body in the hospital, the vital organs removed, and the space formerly occupied by them filled with cotton. The plaintiff sued the hospital, and the trial court, after reducing the amount of damages awarded by the jury, gave judgment for the plaintiff. Both the plaintiff and the defendant hospital appealed to the supreme court of New York, appellate division, second department.

The defendant hospital contended that since it was a charitable institution it was not liable unless the plaintiff proved that the hospital actively participated in the unlawful act and that no such proof was presented to the trial court. The defendant apparently relied on the case of *Hasselbach v Mount Sinai Hospital*, 173 App Div 89, 159 N Y Supp 376, wherein a widow sought damages for an unauthorized autopsy on the body of her deceased husband. The court in that case said:

The question is therefore squarely presented whether or not the defendant owed an absolute duty to plaintiff to protect her husband's body against a post mortem autopsy by any person whomsoever and to deliver said body to her in the same condition that it was immediately after death. The plaintiff insists the defendant was under such a duty. We do not so understand the law. Certainly no reported case has gone to this extent.

It is well settled that in the absence of a contrary testamentary disposition the right to the possession of the body of one who has died belongs to the surviving husband or wife or next of kin for the purposes of preservation and burial and that this right is infringed upon by any one who unlawfully mutilates such a body without the consent of the person entitled to the possession thereof (*Darcy v Presbyterian Hospital* [in City of New York], 202 N Y 259 [95 N E 695 Ann Cas 1912D 1238], *Foley v Phelps* 1 App Div 551 [37 N Y S 471] *Lorson v Chase* 47 Minn 307 [50 N W 238 14 L R A 85 28 Am St Rep 370]) and for a violation of this right damages may be recovered for the injury to the feelings and the mental sufferings resulting from the unlawful act. In all the cases however in which such a right of action has been upheld the person held liable has either been the one who committed the unlawful act as in *Foley v Phelps* or one who caused or procured the autopsy to be made as in *Darcy v Presbyterian Hospital*. None of them therefore are authority for the proposition contended for by the plaintiff in this action.

The plaintiff in the *Hasselbach* case, observed the court, failed to allege in her complaint that the autopsy was performed by the defendant hospital, or by any of its servants or by its consent, knowledge, privity or procurement. In the case under consideration, however, the plaintiff, in substance, alleged in her complaint that the unlawful act was committed by the defendant, its agents or employees while the defendant had the exclusive and absolute possession and control of the body. The *Hasselbach* case is therefore not in point, the court pointed out.

Another case cited by the defendant hospital, *Phillips v Buffalo General Hospital* 239 N Y 188, 146 N E 199, involved an injury to a patient through the alleged negligence of an orderly, engaged in nursing. In the present case the plaintiff was not a patient of the hospital said the court, and her action was based not on mere negligence but on a separate

and independent tort, namely, the unauthorized mutilation of her deceased husband's body. The reasons that have led to the adoption of the rule that a charitable institution is immune from liability to patients because of the wrongful act of its servants are not applicable when the sufferer is not a patient. The plaintiff in this case charged that the defendant hospital had interfered with her right to receive her deceased husband's body whole and un mutilated. Testimony that the body was mutilated and its vital organs missing at the time the undertaker received it at the hospital was uncontradicted. The defendant hospital placed in evidence its rule that autopsies were performed at the hospital only with the written consent of the family of the deceased, and then only by the pathologist. The pathologist testified that he did not perform the autopsy or direct it to be performed. Each member of the staff denied that he had performed the autopsy.

In the opinion of the Supreme Court, a hospital should not be held as an insurer of the safety of a dead body in its possession nor should it be held liable because of the mutilation of a body in its possession by any person or from any cause whatsoever. The evidence in this case clearly showed that the body was mutilated while in the exclusive possession and control of the hospital. The plaintiff, of course said the court, could furnish no proof as to who did the unlawful act. The defendant hospital disclaimed all knowledge of this particular autopsy and called attention to its rules concerning the performance of autopsies. These rules, however, were not observed or in force in this instance, and might have been nonexistent so far as the plaintiff was concerned. The defendant, which should have knowledge of all the facts, did not show that some person pursuing an independent calling and not acting under the authority or direction of the hospital performed the autopsy. The defendant alone knew what transpired within its walls during the night and morning following the death of the plaintiff's husband. A hospital has the means to exercise control over what goes on within its building. Requiring it to take some precaution to prevent the unlawful mutilation of deceased patients, said the court is not placing an undue burden on it, and it should not be allowed to avoid all liability by professing ignorance of what has happened within its own confines. In view of all the facts, it was possible concluded the court, for the jury by reasonable inferences to find that this unlawful autopsy was performed by the direction or with the consent, knowledge or permission of the defendant hospital. The judgment in favor of the plaintiff was consequently affirmed—*Gratwander v Beth Israel Hospital Ass'n* (N Y) 272 N Y S 171.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1935 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Congenital Polycystic Kidneys C Thorrington Montgomery—p 218

Craniocerebral Injuries and Complications—Littlejohn points out that cranial trauma is rapidly on the increase and that probably 15 per cent of the admissions to city hospitals present injuries of the head. Most of these show involvement of the nervous system. Loss of consciousness, for a few minutes or longer, occurs in probably 95 per cent of the cases of fractured skull. Treatment should be directed primarily toward relief of increased intracranial pressure. These patients should be put to bed immediately, and, if there is coma for any appreciable length of time, they should remain in bed for six weeks or longer. Conservative treatment of simple, uncomplicated skull fractures is indicated. Examination should be made for hemorrhage or leakage of cerebrospinal fluid from any of the cranial orifices. Careful neurologic examination for cranial nerve paralysis or paralysis of the extremities is essential. Unless there is a compound fracture, diagnostic spinal puncture should be done. Hypertonic solution of dextrose, given intravenously, is most valuable in reducing the intracranial pressure. Morphine is liable to obscure important diagnostic signs and in addition raises the intracranial pressure. Intracranial hemorrhage must be guardedly anticipated and cannot always be shown by spinal puncture. Immediate debridement is imperative in compound fractures. Hemorrhage may complicate severe concussion, obscuring the diagnosis. Posttraumatic epilepsy must always be anticipated. Posttraumatic sequels are the rule rather than the exception following injuries of the head. Sequels persisting more than eighteen months are probably permanent. Many of the sequels may be forestalled. The conclusions and suggestions that the author sets forth have resulted from the observations of 1,000 patients seen with major craniocerebral injuries over a period of seven years.

Histopathology of Coloboma of Choroid—Folk reports the microscopic study of a coloboma of the choroid. In this specimen, no inflammatory products or mesodermal strands were

found in the region of the coloboma. Retinal folds seemed to be the cause of the formation of the latter, thus supporting the ectodermal theory of coloboma formation. The defect at the disk was not in the optic nerve or its sheath but at its entrance. The choroid and pigment epithelium were absent, the retina was in a state of maldevelopment but showed no fatal gap.

Biopsy in Bone Sarcoma—Ewing offers the following considerations in support of the fact that biopsy should be the last step in the diagnosis of bone sarcoma. 1 The clinical history and the roentgen observations in experienced hands yield a practically certain diagnosis in the great majority of cases. When the clinician forms the habit of relying on a hasty biopsy, he invariably forms the habit of a hasty review of the clinical and roentgen evidence, and thus a vicious circle is established and the actual need of a biopsy tends to increase. 2 The whole clinical and roentgen picture of the case of bone sarcoma usually furnishes a better conception of the diagnostic and therapeutic problem than can be obtained from a biopsy. The pathologist works under a great handicap when he undertakes to make clinical diagnoses and advise treatment without full knowledge of the clinical and roentgenologic data. 3 Few surgeons realize the limitations in the histologic diagnosis of bone tumors and the conditions that simulate or accompany them. The sources of error are numerous. 4 Numerous unexpected complications arise from biopsies on bone tumors and, while the individual surgeon may claim that he has not encountered them very often, the total damage done forms a serious objection to the biopsy. There may be uncontrollable hemorrhage requiring immediate amputation or a more serious emergency measure than the simple biopsy. Infection may follow either low grade and chronic or acute and serious. In any such case, treatment by any other than surgical measures

is generally precluded. The biopsy interferes with proper radiation treatment. 5 Bone sarcomas are allowed to run along in the hands of all types of practitioners until the disease becomes so obvious that no further delay can be tolerated and resort is finally had to the roentgenograph and then to the biopsy. So long as this attitude prevails, there will be few cures of these diseases. When the disease reaches the biopsy stage it is often disseminated in the neighboring veins or already in the lungs. When the condition is readily recognized in the roentgenogram also it is often disseminated. Unless the policy of suspecting bone sarcoma on clinical signs is adopted, the chief of which is persistent pain, worse at night, the melancholy history of this disease will be indefinitely perpetuated. 6 An aspiration biopsy by an 18 bore needle has been remarkably successful in revealing the structure of bone tumors. Most objections to the surgical biopsy are avoided. When this method becomes a familiar routine, there remains a restricted field for the old surgical biopsy.

Preoperative Irradiation in Bone Tumors—Bloodgood gives a brief review of the evidence that justifies giving every suggestive lesion of bone, even before biopsy, a course of irradiation and a thorough course, with high voltage x-rays, or a 4 Gm pack, or larger amounts of emanations in packs. The majority of pathologists, radiotherapists and operators favor and practice this preliminary preoperative and prebiopsy irradiation. It should not be carried too far, at least before biopsy. If distinct improvement does not occur after the first thorough course of treatment, the tumor should be explored or aspiration biopsy performed (for microscopic section). If there is any doubt about the nature of the lesion, sections should be submitted to a number of pathologists of great experience in the study of bone tumors. The case should be registered with the American College of Surgeons. During this time, from one week to one month, the second course of irradiation may be given or there should be a period after the first irradiation of at least two weeks in which no operation, except biopsy, should be done. So, if there is no improvement after the first irradiation, there can be a biopsy immediately, and one will have at least two weeks to get the pathologic view.

Irradiation of Osteogenic Sarcoma—Coley states that of seventy patients with osteogenic sarcoma treated by irradiation sixty-four are dead. Of the six patients known to be alive, four have fibrosarcomas and one a sarcoma developing on an old osteitis fibrosa cystica, and the remaining case is by roentgenographic appearance a sclerosing osteogenic sarcoma but lacks histologic confirmation. Of the six patients, only one has survived more than five years. At present the author feels that irradiation should be offered in preference to amputation only (1) when of doubtful operability, (2) when the histologic picture suggests definite radiosensitivity, (3) when a small periosteal lesion affords opportunity for combined external and interstitial irradiation and (4) in medullary osteogenic fibrosarcomas of low malignancy. All inoperable cases and those in which amputation is refused should receive thorough, well planned irradiation. If improvement is noted, it should be an indication for further use of irradiation up to the limits of skin tolerance. At present prolonged treatment by the fractional dose method is favored by the author. With few exceptions his results in the treatment of pulmonary metastases have not been encouraging.

Procedure in Twisted Ovarian Cyst—Davidson believes that the following procedure will tend to prevent a fatal termination in twisted ovarian cysts from cerebral embolism. The abdomen is opened and explored. The patient is placed in a Trendelenburg position. The cyst is delivered. There may be one or more twists in the pedicle. It may or may not show stagnation of blood, discoloration or even necrosis. The cyst should not be untwisted. The cyst is held in one hand and with the other a Kelly hemostat is placed well below the last twist on the broad ligament. This should be beyond any discoloration or hemorrhagic areas in the pedicle. A suture ligature is placed in the broad ligament beneath the hemostat. The untwisting of the cyst before amputation allows its material to get into the circulation and cause embolism. The cyst is amputated between hemostat and suture ligature and repaired as usual. The abdomen is closed in layers.

Amyloid Degeneration of Adrenals in Tuberculosis—Bronfin and Guttman found eighteen cases of amyloid disease in a series of 100 tuberculous patients that came to necropsy. Of these, fourteen showed also amyloid infiltration of the adrenals involving mainly the cortex. Clinically, they could be classified into three groups. In the "positive group" there were five patients in whom a diagnosis of Addison's disease was made during life. Of these, one patient was temporarily benefited by the administration of cortical extract and another by the Muirhead regimen. In the second group there were suggestive symptoms of Addison's disease but a diagnosis was not warranted, and the third group did not show any symptoms of Addison's disease during life. Histologic study of the adrenals in those cases seems to show a definite relationship between the extent of amyloid involvement of the adrenal cortex and the symptomatology, notably the asthenia and gastro-intestinal symptoms. Attention is called to the possibility that in many cases of far advanced pulmonary tuberculosis there are symptoms of Addison's disease which are usually unrecognized and attributed to the existing tuberculosis. The recognition of these symptoms should prove helpful not only by way of therapy when cortical extract becomes available commercially but also to prevent the institution of surgical procedures, which invariably hasten a fatal termination in such cases. In the light of this study, amyloid of the adrenals, which, as a rule involves only the cortex, should be given a better recognized position in the etiology of Addison's disease.

Roentgen Technic for Double Exposure of Chest—Sampson outlines a roentgen technic for double exposure of the chest in which one half of each film is covered with a sheet of lead of sufficient thickness to ensure protection. The unprotected side is then exposed to register the "good" lung. The protecting lead is then shifted to the half of the film that now has a registration of the "good" lung. The cassettes are then placed in either a horizontal or a vertical Potter-Bucky grid apparatus. To obtain proper perspective, the case used with the tube in the high position for the good lung must be used again with the high tube position for the compressed lung. The exposure for the dense side will depend somewhat on how great the density is. For heavy densities a spine technic is used and for lighter densities the exposure is shortened. Because there is little or no movement on the "diseased" side reasonably long exposures (approximately five seconds) do not appear to be objectionable. However, the shorter the exposure the less danger there is from blurring caused by motion. A small focal-spot radiator type of Coolidge tube is used to compensate for the short focal spot film distance, which is to a great extent determined by the type of Potter-Bucky grid used. An average technic is kilovolts variable 10 milliamperes, distance of 30 inches and time of five seconds. The kilovolt is varied for different depths of chests. The perspective on the Potter-Bucky grid side of the film is usually satisfactory and one is able to evaluate the relative position

of pulmonary and thoracic structures. However, too much reliance should not be placed on it if further surgical procedure is contemplated, unless the surgeon and the roentgenologist can check the perspective by known anatomic landmarks. The author has not attempted to evaluate statistically the foregoing method. It has become a routine procedure when one side of the chest is dense and the opposite side is amenable to the usual chest technique.

Complement Fixation in Experimental Tuberculosis—In his experimental work with tuberculosis, Baker observed that vaccinated rabbits can be definitely differentiated from the nonvaccinated controls by the aid of the complement fixation test. The antibody titer in vaccinated animals does not measure the existing allergy but does appear to parallel the resistance of the animals to experimentally produced tuberculosis. The humoral antibody produced by vaccination is not destroyed when it cannot be detected by the complement fixation test but leaves the circulation and can be exfoliated by various stimuli.

Insulin Hypoglycemia.—Dameshek and Myerson studied the mechanism of the neurologic symptoms of insulin hypoglycemia in man, chiefly by comparing the contents of dextrose and oxygen in the vessels supplying the brain and the arm before and after the intravenous administration of insulin. The chemical changes in the blood usually varied directly with the severity of the reaction. The uptake of dextrose by the brain (as measured by the difference in the dextrose content of an artery and the internal jugular vein) became materially reduced during the severe hypoglycemic reaction, although that of the arm usually became increased. The uptake of oxygen by the brain (as determined by arteriovenous differences in the content of oxygen) varied indirectly with the severity of the insulin reaction, becoming much reduced during the most severe reactions. The blood lactic acid became increased during the reaction, no differences between vessels being noted. The spinal fluid pressure regularly became increased before the objective phenomena of the hypoglycemic reaction could be seen. There was no essential change in the dextrose content of the spinal fluid during the period of observation (from forty-five to ninety minutes). The pulse pressure usually became increased, owing to a slight rise in systolic pressure and to a more marked fall in diastolic pressure. An injection of epinephrine regularly diminished the symptoms of the insulin reaction. The marked diminution in the arteriovenous difference in the content of oxygen during the severe insulin reaction may signify actual diminution in the uptake of oxygen by the brain and arm. If this is true the neurologic symptoms of the insulin reaction may be due to the effects of a lack of oxygen on brain tissue.

Changes in Cerebral Cortex Produced by Thermocoagulation.—Dusser de Barenne and Zimmerman discuss the changes in the cerebral cortex produced in monkeys by thermocoagulation through local application of heat at from 56 to 80 C for short periods of time. The most suitable temperatures for laminar thermocoagulation of the cortex are from 65 to 80 C. The depth of the lesion depends on the temperature applied and the duration of the application. Following thermocoagulation at a temperature between 65 and 80 C, all the nerve cells have disappeared in the heated area after thirty-six hours. After from seven to twelve days the heated area

appears as a devastated region, sharply delimited from the normal surrounding cortex by a wall of proliferated glia and fibroblasts. Inside the heated area the glia cells are still present and staining after twelve days. Application of lower, though still supernormal, temperatures to the cortex results in typical changes. Even the application of 50 C for half a minute to the cortex results in the death of all the nerve cells in the heated area; they have disappeared after thirty-six hours. It is of interest that in the chronic preparations (survival period of four months) the whole devastated area has disappeared. Not only the nerve cells but also the neuroglia, the blood vessels, the interstitial tissue and the wall of proliferated glia and fibroblasts have disappeared. This fact proves that the glia present and staining in the "acute" preparations is no longer alive but also has been killed by the thermocoagulation. Scar formation and retraction of the adjacent cortex are absent in "chronic" preparations. This observation suggests the usefulness of this method in neurosurgical procedures on man.

Operative Mortality in Exophthalmic Goiter.—Thompson and his associates believe that, apart from surgical skill, the most important factor in determining the risk of thyroidectomy for exophthalmic goiter is the preoperative condition of the patient. Great attention should be paid not only to the administration of iodine but also to emotional instability, muscular weakness, rest, body weight and infection. The two most important factors in gauging the risk of operation, regardless of the height of the basal metabolism, would appear to be emotional instability and muscular weakness. When the two are marked in the same patient, an unfavorable outcome of the operation is common. Because of the beneficial effect exercised on the course of the disease by rest, patients should be prepared for operation in the hospital. In patients in whom the disease is refractory to iodine, roentgen treatment may be used to prepare the patient for operation, but this form of therapy should never be used in desperately ill patients because it produces a temporary increase in the severity of the disease. The treatments should not be given at intervals of less than one week and no improvement should be expected in most cases for a period of several weeks. A gain in body weight is a favorable sign, therefore the caloric intake in most cases must exceed the basal by at least 100 per cent. Following mild

infections of the upper respiratory tract, no operative procedures should be carried out for at least two weeks after the temperature is normal, and following severe infections of the upper respiratory tract for at least four weeks. The criteria for gaging the risk of operation are the same in patients who have cardiac irregularities as in those who do not. The time to prevent postoperative crises is in the pre-operative period.

Diagnosis of Gallbladder Disease—Hartung and Wachowski present a modified procedure for diagnosis in cases suggesting disease of the gallbladder. The procedure in sixty-three cases was as follows. In most of these cases the dye was administered orally and the patients were first seen by the authors after its administration. Fourteen hours after the oral or six hours after the intravenous administration of the dye, roentgenograms were made and developed immediately. If they were satisfactory and showed a good outline of the gallbladder of approximately normal density, the patient was given a meal consisting of egg yolks and cream. Otherwise additional roentgenograms were made after an interval before the fat meal was administered. One hour after the fat meal, roentgenograms were made to show contraction or other observations that might be of value. An opaque meal was then given under fluoroscopic control and special attention was paid to possible secondary signs. Subsequent examinations were made in individual cases in which additional information might be obtained thereby. A written report was then incorporated with the history of the patient and if the patient came to operation, this was compared with the surgeon's observations. No attempt was made to ascertain the exact nature of the pathologic condition present when a pathologic gallbladder was reported. Special stress was placed on adhesions or other changes that might explain the roentgen signs observed. Of these, evidences of abnormal fixation, gallbladder 'seats' and functional disturbances were recorded, although note was made if other abnormalities were present. Correct diagnoses were arrived at in more than 96 per cent of the cases. In forty-two of them the same conclusions may have been reached from the cholecystographic examination alone. In the other twenty-one, secondary signs elicited from the opaque meal examination prevented errors in diagnosis in almost half of them which would have been made if the observations obtained from the dye test had been the sole criteria.

Unusual Case of Primary Tumor of Ureter—Colston reports a case of primary papillary epithelioma of the ureter with the complication of implantation in a probably preexisting bladder diverticulum. The treatment consisted of nephrectomy followed by complete ureterectomy nine months later when the correct diagnosis was made. Six months after the second operation, the diverticulum containing the tumor implant was removed. The correct diagnosis was not made until persistent bleeding from the ureter was discovered by cystoscopic examination and the ureterogram presented a typical picture. That complete nephro-ureterectomy is the method of choice and should be employed for all patients whose condition will permit

this operation is the conclusion of all observers. The inadequacy of many methods of so called complete nephro-ureterectomy is emphasized, since the mucous membrane of the distal stump of the ureter is not removed or destroyed. The extreme importance of complete eradication or destruction of the entire ureteral mucous membrane, especially the portion in the intramural part of the ureter where tumor implantation has been shown to occur, is emphasized. A method of complete ureteronephrectomy, combining the previously well known steps but adding the heretofore unreported technic by which the mucous membrane of the distal stump of the ureter through out its whole course through the bladder wall is completely destroyed with the high frequency current, is reported.

Effect of Digitalis on Cardiac Dilatation Produced by Anoxemia—Van Liere and his co-workers subjected twenty-three normal dogs to anoxemia of various grades of intensity so as to produce cardiac dilatation. They found that, if these animals were given digitalis and again subjected to anoxemia the amount of cardiac dilatation was appreciably lessened. The action of digitalis was more efficacious in the less extreme ranges of anoxemia, although even in very severe degrees of anoxemia it exerted a distinct influence. Differences in cardiac rate could not account for a smaller heart after digitalis had been given and anoxemia administered, as the heart actually beat slower. Even though this allowed more time for relaxation, the cardiac silhouette was smaller. If the vagi were cut however the heart beat much faster and the more striking results obtained during anoxemia when the vagi were sectioned could be explained by a more rapid heart. Venous pressure readings could not explain the smaller cardiac silhouette, as digitalis in the normal dog produces slight changes in the venous pressure. It was felt that digitalis acted directly on the cardiac musculature so that the tone of the heart was increased and the contraction was more complete. The muscle fibers were capable of withstanding greater strain and so allowed less cardiac dilatation. The effect might be the same or even be more striking in certain types of abnormal hearts. The data suggest in view of the clinical reports of Kaufmann and Meyer and those of Somervell that it might prove beneficial to administer small but effective doses of digitalis as a

prophylactic measure to certain patients who will be exposed to high altitudes and who have not been properly acclimated.

Sodium Formaldehyde Sulphoxylate in Mercurial Poisoning—Brown and Kolmer were unsuccessful in their endeavor to corroborate the results obtained by Rosenthal with sodium formaldehyde sulphoxylate in mercurial poisoning. In their experiments, using only the minimal lethal dose of mercuric chloride, they had but indifferent success in saving the rabbits with sodium formaldehyde sulphoxylate. If the mercury is allowed to get a sufficient start, the antidote is of no value in saving the rabbits. That is, if a single intravenous injection of the antidote is not administered before the kidneys have become irreparably damaged, a second injection is apparently of no avail. Intravenous injections are unnecessary as good results were obtained if the sulphoxylate was administered by mouth within the time necessary to prevent absorption of sufficient mercury to be toxic. Evidence of a direct alleviating action of sulphoxylate on the kidneys was not obtained. Repeated injections have never prevented the death of any rabbits from nephritis if the first injection has been given more than one hour after the mercuric chloride has been administered. The primary action of the sulphoxylate is apparently its reducing action, the effect being to decrease the amount of corrosive mercury absorbed by the formation of insoluble metallic mercury. Of the rabbits that survived as a result of the administration of sulphoxylate, all showed some increase in urea nitrogen, which ranged from about twice normal in those animals in which the antidote was administered just before the mercurial to about five times normal when the antidote was given after the mercurial. In the surviving animals, all the urea values returned to normal in from three to five days. The authors believe that the chief value of sodium formaldehyde sulphoxylate as an antidote in acute mercurial poisoning lies in its use by mouth in sufficient quantities and sufficiently early. Intravenous treatment should be used cautiously and in somewhat lower dosage than that recommended by Rosenthal in order to prevent complications due to the fact that the sulphoxylate is more toxic to a person poisoned by mercury than to a normal organism.

Malignant Neutropenia—Gordon believes that the absolute etiology of malignant neutropenia is still unknown. The apparent best results obtained in its treatment have been through the use of blood transfusions, nucleotides or their derivatives and roentgen therapy. Possibly these forms of treatment have the same effect on the system by giving to it the products of the destroyed nucleus which are necessary in the production of the white blood cell. The routine in treatment that the author has followed and found to be most successful includes the general and specific forms of therapy that lead to an increase in nuclein or its by-products. General

systemic stimulation is given, accompanied by intravenous dextrose and saline solution, mouth washes, irrigations and oral hygiene. A high nuclein diet is given. Small blood transfusions of whole or citrated blood have been most valuable. When there are signs of jaundice or of liver exhaustion, blood transfusions should not be given. Whole blood (40 cc.) is given intramuscularly twice a day in the same site of injection. The irritation of the muscular tissue probably produces a substance that stimulates the bone marrow. Also it is of value because a concentrated form of nuclear material is given to the body. Another reason is that possibly a substance exists in the normal blood that is lacking in the patient having malignant neutropenia. Nucleotide and nucleic acid are next in importance in the treatment. This produces an irritating stimulation and supplies a concentrated form of nuclein to the body to stimulate the production of white blood cells.

Retinitis in Diabetes—Wagener and his associates observed that of 1,052 patients having diabetes 177 per cent had hemorrhagic lesions of the retina, 55 per cent hemorrhage alone and 12.2 per cent hemorrhage associated with exudates. They believe that the very existence of retinitis in cases in which patients have no other signs of vascular disease must mean that diabetes alone does something to injure the finer arterioles or venules of the retina. The retinal disease in question seems to pass progressively through successive stages, beginning with hemorrhages only and eventuating in very evident disease of the veins. The final stage is manifested by hemorrhage into the vitreous and the fully developed picture of retinitis proliferans. Injury to the retinal vessels may occur in all cases of diabetes. If so, it is insufficient in degree in most cases to bring about visible abnormalities in the vessels or to give rise to actual hemorrhages or exudates. In a few cases it does do so, and when the circulation of the retina is

adversely influenced by the presence of arterial or arteriolar sclerosis, it is more likely to be manifest. In that case a lesion characteristic of diabetes is added to a retinal vascular lesion otherwise characteristic of hypertension, this gives a composite picture from which the trained observer can diagnose diabetes. By what means diabetes injures the retinal vessels in this characteristic manner, whether because of its accompanying hyperglycemia or hypercholesterinemia or because of the presence intermittently of the products of ketosis, the authors cannot say. The lesions are observed in cases of mild diabetes as frequently as in cases of severe diabetes, in those in which insulin is used as well as in those in which diabetes is controlled without insulin, early in the disease as well as late, although more frequently late, and when the carbohydrate of the diet has been unlimited as well as when it has been restricted and more fat has been fed. The possibility occurs to the authors that lesions like those observed in the retina may also occur in the peripheral nerves and thus account for the high incidence of peripheral neuritis among patients with retinitis.

Newer Methods of Malaria Control—Wynne bases his statements on his experience in treating 476 cases of malaria. Of the 159 completed treatments, sixty-nine were tertian and ninety estivo-autumnal. One patient had both tertian and estivo-autumnal parasites. The following treatment was carried out as closely as possible in all cases. A thick smear of the patient's blood was taken. He was given sufficient acetylsalicylic acid to control temperature, a purgative, and one tablet of atabrine before each meal for five days. Alcoholic drinks were prohibited and the diet was restricted to one-half the usual amount of meat. If the blood was estivo autumnal positive, the patient was given atabrine, one tablet before each meal and one-sixth grain (0.01 Gm) of plasmochin three times daily, the dietary instructions were the same as for the tertian type. The patient with the mixed infection was given atabrine and plasmochin. Of the 159 patients treated with atabrine and plasmochin, 152, or 95.6 per cent, had a negative report on every blood test for the required five weeks. Of the remaining seven, all of whom had tertian malaria, one had a positive blood test the second week when atabrine was repeated, the blood remaining negative since, two had a positive blood the fourth week, received atabrine and have been negative since completing the second treatment, a fourth patient, who had a relapse, has been given three atabrine treatments and is still under observation. Relapses occurred in the three remaining patients, each having a distinct malarial paroxysm and positive tertian blood, receiving 60 grains (4 Gm) of quinine in twenty-four hours, then atabrine, and having had negative blood tests since. Of the cases treated with quinine, the results are as follows. The six patients given intravenous quinine and the twelve treated intramuscularly had no relapses and no bad results from the drugs as given. As for the 159 cases treated with 20 grains (1.4 Gm) of quinine daily by mouth, there were seventeen relapses during the course of the treatment or while quinine was being taken and eight relapses within two weeks following completion of the treatment. Of the group treated with 20 grains (1.4 Gm) of quinine magnesium sulphate solution, there were seven relapses during treatment and six relapses within two weeks following completion of the treatment.

Influence of Vitamin B₂ on Hematopoiesis in Anemia.—Smith and Stohlman compared the rate of hemoglobin and red blood cell regeneration in animals with a standard degree of anemia under adequate dietary conditions with that under conditions of B deficiency. Albino rats were used. The type of experimental anemia was produced by means of phenylhydrazine. In the normal rat this anemia is transient in character, complete recovery taking place in about ten days. The early stages of recovery are accompanied by pronounced reticulocytosis. Elimination of the B₂ vitamin from the dietary of the rat does not materially affect the progress of recovery from the standard phenylhydrazine anemia. Vitamin B₂ does not appear to be concerned with hematopoiesis in the albino rat.

Cardiac Contusions—Elkin reports three cases of cardiac contusion. The most common cause of such an injury is an automobile accident in which an individual is suddenly thrown forward against the steering wheel. The sternum and ribs may be broken and their ends directly injure the heart, or the sudden compression of the heart may injure it, although a break has not occurred. The three cases reported are exam-

ples of nonpenetrating cardiac injuries in which recovery took place. Any patient who is struck in the chest must be suspected of such an injury, particularly if such symptoms as precordial pain, dyspnea and tachycardia are present. Persistence of these symptoms, together with irregularity of the heart, cyanosis and a peculiar tick-tick quality of the heart sounds, makes the diagnosis almost certain. The treatment is symptomatic. The chief reliance is to be placed on morphine and sedatives for quiet and rest, and on oxygen for dyspnea and cyanosis.

The Pathology of Milk Anemia—Von Hram describes the pathologic changes in albino rats suffering from goat's and cow's milk anemia. Hypertrophy of the cardiac muscle, atrophy of the spleen and fatty degeneration of the liver were the most characteristic gross anatomic features. Histologic study confirmed the gross pathologic observations and showed as the only differential diagnostic sign between the two types of anemia a disturbance of leukopoiesis in the animals fed with goat's milk. The pathologic changes in goat's milk anemia are not similar to the pathologic observations in human cases of pernicious anemia, and any near relationship between the two types of anemia has to be declined. Control animals showed none of the foregoing changes, which therefore can be regarded as characteristic of nutritional anemia in the albino rat.

Typhoid Spine—Gambee says that diagnosis of typhoid spine is based on an unmistakable history of typhoid, followed weeks or months or years later by a painful sore back. If the history affords no other explanation for the pathologic changes and the roentgenogram reveals dense bony deposits in the intervertebral ligaments or destruction or narrowing of one intervertebral disk, the diagnosis is quite probable and becomes more certain when the Widal test is positive. The author reports a case in which a vertebral abscess developed four years after the patient had apparently recovered from a typhoid spine. The operation that he resorted to in draining the abscess represents a new departure in the management of this complication of typhoid. The patient was given a general anesthetic and an incision was made along the lower border of the twelfth rib on the left, forward to the outer border of the rectus and then downward far enough to give free exposure. The parietal peritoneum was stripped mesially, the sigmoid and other intra-abdominal viscera being taken with it. The infiltration of the soft tissues made it easy to identify the involved part of the spinal column. These superficial soft tissues were incised close to the abdominal aorta and a pocket containing about 10 cc. of yellow pus was entered. Cultures of this pus were taken. Roughened bone constituted the floor of the abscess which was definitely circumscribed. A drill hole was then made through the center of this exposed bone and it was found that the bone was only egg-shell in thickness and that there was an underlying round abscess about 2 cm in its greatest diameter. It also contained yellow pus. Cultures of this pus were taken. The abscess evidently lay between the two abutted vertebrae. A Penrose drain was placed in the abscess and taken out through a stab wound just above the left anterior superior spine of the ilium. The wound was then closed in layers without further drainage. The patient recovered rapidly. The wound healed without infection and at the end of four days the patient's temperature was normal. He left the hospital on the tenth postoperative day. There still was a small amount of drainage. Ten weeks later roentgenograms showed considerable bone repair. The operation is proposed as a rational way of handling osteomyelitis of the lumbar vertebrae, whether caused by typhoid bacilli or by pyogenic organisms.

Congenital Dermal Sinuses—Walker and Bucy cite seven cases. A congenital dermal sinus manifested externally by a small dimple in the midline of the back, becoming infected, discharges periodically serous or purulent material. This sinus extends to the meninges and its lumen acts as a pathway for infection to reach these structures. When this occurs, producing abscess formation, fever develops, the back becomes painful and rigid and the neck becomes stiff. Weakness of the lower extremities ensues, but sensory disturbances are slight or absent. The spinal fluid, usually sterile, shows a pleocytosis. Surgical removal of the sinus and subdural abscess with drainage produces a complete cure in almost every case. The relation of this congenital dermal sinus to spina bifida occulta is discussed and the incidence of the latter in a series of 7,500 roentgenograms taken of the spine in a general medical and surgical clinic is given. The etiology of these congenital dermal sinuses and pilonidal cysts is discussed.

Localized Abnormal Sweating on Eating—Uprus and his co-workers submit the case of a woman, aged 22, in whom at the age of 5 glands were removed in the right side of the neck through a horizontal incision over the middle of the sternocleidomastoid muscle. One year later, when she was eating, well localized flushing occurred in the right submental region—a triangular area bounded medially by the midline, laterally by the ramus of the jaw to a point 1 cm in front of the angle of the jaw and posteriorly by the line of the hyoid bone. With the responses of the skin of the face and the normal side of the chin when indifferent limbs were heated taken as controls the response of the abnormal area is definitely pathologic. When the patient ate, flushing indicative of vasodilatation in the abnormal area occurred even when vasoconstriction was in progress. The same stimulus that produced salivation caused a combination of vasodilator and secretory phenomena in the abnormal area of skin independent of general vasomotor activity. The stronger the stimulus for salivation, the more rapidly did the abnormal skin reaction occur. Anesthetization of the abnormal area by blocking the nervus cutaneus colli was ineffective in stopping the abnormal reaction. On anesthetization of the lingual nerve with the chorda tympani the abnormal reaction of the vessels and sweating in the right submental region were not observed. The anesthetization of afferent pathways might be invoked to explain the failure of this response, but the authors are convinced that stimuli from either side of the mouth were equally effective, and no difference in response was observed when half the tongue and the gums and cheek of the right side were cocaineized. The efferent pathway would therefore appear to be in the chorda tympani. The chorda was involved by the anesthetization since observation of the orifices of Wharton's ducts in the floor of the mouth showed profuse salivation from the left side and none from the right. The period of latency between the original trauma and the onset of symptoms is consistent with an unusual regenerative phenomenon having occurred.

Hypothesis of Kidney Mechanism—M Clure suggests a modification of Cushman's hypothesis of kidney mechanism. The stage of ultrafiltration is assumed. But instead of pure reabsorption in the tubules it is supposed that the cells reabsorb substances relatively valuable to the body and simultaneously secrete unwanted substances and further that the amounts of material reabsorbed and material secreted are in equilibrium—in other words, that an exchange is effected by the kidney cells as between the filtrate and the general blood stream. An equimolecular basis is assumed for the exchange that an equivalent amount of solids is simultaneously secreted to take the place of solids reabsorbed. The idea of mixed reabsorption and secretion in the tubules is not new. It has been suggested by Wilkinson. The only difference is that the author is assuming a numerical relationship between the two processes in order to put the resulting theory on a quantitative basis.

Periodicity of Influenza—To determine the periodicity of influenza, Spear studied the material contained in the "Weekly Return" of the Registrar-General for the last forty-four years. During this period there have been forty-three prevalences or epidemics in London of widely differing degrees of severity, the analysis of which indicates that the conditions associated with the approach of summer exercise a restraining influence on an established prevalence of influenza, but that on the return toward the winter solstice the prevalence is renewed—generally with greater mortality—at a seasonal phase approximately the same as that at which the first prevalence occurred, and that in the case of a prevalence associated with an approaching winter solstice the epidemic impulse is completely exhausted and a year or more of freedom from epidemic prevalence follows. The author gives rules that enable an approximate forecast of a prevalence to be made.

Surgical Aspects of Spastic Colon and Prediverticular State—D'Abreu studied four cases shown roentgenographically to be in the prediverticular state unaccompanied by diverticulosis and in which laparotomy was carried out because of pain and the passage of blood and mucus. In one of the cases laparotomy was done under general anesthesia and no abnormality was discovered. A barium sulphate enema taken some months later showed the appearance of prediverticulosis. Abnormalities of the prediverticular stage during life can be studied only under spinal anesthesia. Peristalsis in the large intestine

depends on the automaticity of the muscular fibers, the myenteric plexuses of Meissner and Auerbach and nervous impulses from the vagus and the sacral parasympathetic, relaxation, except in the case of the sphincters, depends on sympathetic nervous influences. General narcosis paralyzes the parasympathetic system, while spinal anesthesia, on the other hand, prevents the action of those sympathetic fibers which flow out to the abdominal viscera and either leaves the parasympathetic unaffected and in undisputed domination or more probably allows the intrinsic dynamics of the intestine free unimpeded action. Learmonth has produced evidence that there is a high degree of autonomy in the plain muscle of the intestine and its intrinsic nerves. In portions of intestine in the prediverticular state removed along with areas of established diverticulation, the most notable change seen is hypertrophy of the circular muscle coat which projects as bands into the lumen of the intestine. The author has found hyperchlorhydria present in spastic prediverticular subjects. In cases in which presacral and lumbar colonic neurectomy has been done, subsequent barium sulphate enemas may present roentgen appearances reminiscent of those seen in the prediverticular state. In a series of cases after lumbar sympathectomy had been performed for vasospastic conditions in the legs there is no alteration in the normal barium sulphate enema picture of the intestine. Tobacco smoking frequently aggravates the symptoms of these prediverticular and spastic colon subjects. Nicotine diminishes activity in both the sympathetic and the parasympathetic systems, but as the normal balance favors the vagus and the sacral autonomic outflow, increased activity of the motor function leads to excessive peristalsis and spasticity. Pylorospasm is often present in heavy smokers. The pathogenesis as observed in the change from the prediverticular state to that of diverticulosis leaves little room for a developmental theory of causation.

Guanidine, Dextrose and Calcium Content in Blood in Eclampsia—Krieger correlated the guanidine content in the blood in a series of thirty cases of eclampsia with dextrose and calcium concentrations. No appreciable rise in guanidine was observed. In 33 per cent of the specimens of blood examined the blood sugar value was below 0.8 per cent, although only isolated estimations, without reference to the phase of eclamptic seizure, were performed. This indicated the probability that hypoglycemia did exist at some phase in relation to the convulsion. In 39 per cent of the eclamptic cases the calcium content of the blood was less than 9 mg per hundred cubic centimeters of blood. The statement of Minot and Cutler that eclampsia was characterized by high guanidine associated with low dextrose and low calcium concentration in the blood has thus been disproved.

- *Treatment of Acute Infective Osteomyelitis Plea for Diaphysectomy R A Ramsay —p 581
 Intracranial Calcifications C P G Wakeley —p 586

Diaphysectomy in Osteomyelitis—Ramsay advocates diaphysectomy as the ideal treatment of acute infective osteomyelitis or subperiosteal resection of all that part of the bone which is infected. Such an operation leaves a widely open and at first soft-walled space which is well drained, the soft

walls form new bone in a surprisingly short time and thus new bone does not enclose a large infected dead mass requiring removal at a later date and causing prolongation of the illness. In performing diaphysectomy, the operative details naturally vary according to the bone affected. In all other methods of treatment, large sequestrums are formed and have to be dealt with, and when they are removed large cavities remain which persist for a considerable time and may require repeated operations for their treatment, even so, the end result may be far from satisfactory. Diaphysectomy prevents the formation of sequestrums and does not leave a large, rigid walled cavity, so that the extent of any secondary operations is reduced and the final satisfactory result is attained in a much shorter time than by any other method, therefore it may justly be asserted that diaphysectomy hastens recovery and lessens the number and extent of secondary operations. Diaphysectomy is a radical operation which offers the advantages of life, limb and time saving, and this consideration of the subject is put forward in the hope that this method of treatment may receive the recognition which, in the opinion of the author, it deserves.

Tuberculosis in Relation to Blood Groups—Bradbury believes that tuberculous persons show a higher proportion of blood group 4 than do nontuberculous persons. The difference is appreciable in practice, and he was impressed by the correspondence between blood grouping and diagnosis, in the sense that a doubtful case which was found to belong to blood groups 1, 2 or 3 more often turned out to be nontuberculous than tuberculous. He does not suggest that the test should be used as a routine diagnostic aid, but it appears that it may have some value as such. In carrying out this investigation he has had in mind the possible application of blood group testing to the preventive side of tuberculosis. There is no really satisfactory explanation of the manner in which tuberculosis selects its victims, or of the means by which a husband or wife resists the consequences of infection from a diseased partner. If it is a fact that the blood grouping of tuberculous persons is different from that of nontuberculous persons, it becomes possible

to theorize as to the reasons for this difference. The author is convinced that there is a difference in the blood group distribution of tuberculous and nontuberculous persons. In support of the evidence that he gives to this effect he states that international statistics are available which have a bearing on the matter.

Sedimentation Rate in Kala-Azar—Chung determined the erythrocytic sedimentation rates of thirty-six patients having kala-azar by the time method, and in many cases by the distance method. At the same time the hematocrit value and the plasma proteins were measured in the majority of cases. For control and comparison, the sedimentation rates of fourteen normal persons, nine with miscellaneous diseases, seven with active tuberculosis and fifteen with syphilis were determined. To eliminate the influence of anemia, the blood of twelve patients with kala-azar was artificially converted into a fixed concentration having a hematocrit value of 50 volumes per cent before shaking it up again for the sedimentation test. The sedimentation rate in the fourteen normal Chinese subjects varied from 270 minutes to 3960 minutes by the time method, and from 1 to 7 mm by the distance method. The sedimentation rate was uniformly and markedly increased in all thirty-six cases of kala-azar. This was associated with a decrease in plasma albumin and an increase in plasma globulin, euglobulin and fibrinogen. After correction for the anemia that was present, the sedimentation rate was still uniformly above the normal value. The factors possibly involved in this phenomenon are discussed.

Autovaccines in Pylonephritis of Pregnancy—Trillat has treated patients with pylonephritis of pregnancy by means of autovaccines made with organisms from the urine. In preparing the vaccines, one should use a relatively short time (maximum of twelve hours) of incubation to avoid abnormally high numbers of colon bacilli. The ampules contain 2 cc. of the vaccine with two, three or four billion bacteria per cubic centimeter. The vaccines are administered subcutaneously, beginning with a dose of 0.5 cc. and increasing 0.5 cc. at a time until 2 cc. is given. Individual variations in dosage are sometimes necessary. The treatment should be begun early and should be prolonged. The majority (seventeen) of the author's cases of pylonephritis were pure colon bacillus infections. Only one case of pure enterococcus infection was treated successfully. All the others were mixed infections. No complications of severity were noted from the vaccine treatment. Five results were excellent and seventeen satisfactory, three patients were lost from view and in three no results were obtained. One of the last three died from septicemia. Usually there was some improvement between the third and sixth injections, pain is the first to recede, then the temperature drops and the urine becomes clarified but the bacteriuria persists for a relatively long time. The author feels that autovaccine therapy has given some remarkable results and is virtually indicated in all pyelonephritides.

Delayed Rupture of Amnion—Numerous factors, according to Leon, determine the moment of rupture of the bag of waters. The principal one is the mechanical and depends on the relation existing between the intra amniotic pressure during uterine contraction and the elastic properties of the membrane. In delayed rupture, however, the preservation of the amniotic sac is more than merely increased resistance of these tissues alone. The author has attempted to reconstruct the existing conditions by means of an experimental apparatus consisting of connecting chambers representing the forces of the segments of the uterus and the amniotic sac. As a result he believes that transverse expansion of the inferior segment (without marked elevation of the contraction ring) explains the failure of the sac to rupture by increasing the resistance. This is the most common explanation for delayed rupture.

 *Peripheral Facial Paralysis Treated by Cervical Ganglionectomy T Ostrowski and W Dobrzaniecki —p 16
 *Experimental Studies and First Clinical Application of New Operation Designed to Increase and Equalize Neuromuscular Function in Partial Nerve Paralysis A M Doghotti —p 30
 Massive Removal of Cancerous Breast and Supraclavicular Glands. Technique M Fiolle —p 49
 Resection of Erector Nerves and Hypogastric Ganglions V Richer —p 54

Facial Paralysis Treated by Cervical Ganglionectomy—Ostrowski and W Dobrzaniecki treated five patients with peripheral facial palsy by resection of the superior cervical ganglion. The treatment is based on Leriche's paper of 1919. The clinical reports are given with photographs before and after cervical ganglion resection. One fact emerges clearly from those observations. In a persistent paralysis with complete or even partial reaction of degeneration all medical, physical and electrical treatments merely arouse false hopes and are entirely ineffective. In these cases operative treatment is indicated because a prolonged delay inevitably results in secondary muscular contracture. From the standpoint of clinical results, cervical ganglionectomy constitutes a definite advance in operative treatment since, even with the persistence of neurologic degeneration the external signs of paralysis disappear, thanks to change of muscular forms.

Operation for Partial Nerve Paralysis—Doghotti reviews the knowledge concerning the regeneration of nerve

fibers. He reports experiments on four dogs, operated on under ether anesthesia. After exposure of the sciatic nerve on the posterior side of the thigh, the nerve was sectioned transversely with a razor a few centimeters below the point of exit of the nerve from the sciatic notch. The superior trunk was divided into two parts, one large (about two thirds) and the other smaller. The larger portion was loosened as high as possible by blunt dissection. This portion was then passed through the body of the posterolateral muscle of the thigh and its free end fixed in the subcutaneous tissue. Following this procedure the animals showed the characteristic paralysis due to sciatic section. They were allowed to run several hours a day. A muscular atrophy occurred in the limb operated on in all instances. After three or four months, functional restoration began to appear. After six or seven months the muscles had reacquired a volume almost equal to that of the other limb. Microscopic examination of the muscles and nerves showed that the regenerated myelin fibers of movement had penetrated and were homogeneously distributed in all the fascicles. These observations demonstrate the peripheral anatomic and functional regeneration of the nerve fibers from a decreased central source. A similar section of the left sciatic nerve was performed on a boy, aged 10, so severely paralyzed by poliomyelitis that no other hope of restored function could be considered. After about four years there was increased movement possible in this limb as compared with the other. The author feels that the operation does no harm, may be accompanied by some improvement, and facilitates other therapeutic measures.

Histidine Treatment of Skin Lesions—Craps and Alechinsky treated ten patients presenting certain local skin lesions by direct daily applications of an aqueous solution of 1/1000 histidine. The lesions treated were a trophic ulcer of the crest of the tibia, an infected traumatic ulcer, several varicose ulcers, an ulcerated syphilitic gumma, and an ulceration resulting from the curetting of a large verrucous tuberculous lesion on the palm of the hand. In general, without the use of an antiseptic or other treatment the ulcers became rapidly cleansed and soon took on a good color. Tolerance to these repeated dressings was good. In only one case was improvement not noted.

Artificial Stiffening of Anterior Mediastinum—Rehn shows that the anterior upper portion of the mediastinum plays a special part in the processes of respiration and in the flow of the blood which becomes evident only in space limiting pathologic processes originating in the sternum, the lungs, the organs of the mediastinal space and the loose connective tissue of the anterior mediastinum itself. It is known, from surgical observations that in disorders of this nature a rigid mediastinum shows an entirely different behavior from that of a loose mediastinum. Rehn devised a method by which rigidity of the mediastinum may be induced, and he also perfected a method of mediastinography that involves no danger for the patient.

Artificial stiffening of the mediastinum was done first by injection of rapidly resorbable fluids, such as physiologic solution of sodium chloride or gum solution, but later the author changed to a coagulable, sterile animal plasma preparation, which is absorbed slowly. He was further encouraged in his attempts at stiffening of the mediastinum by Naegeli's cinematographic roentgen film which demonstrated that by means of infiltration of the anterior mediastinum it is possible to prevent, even in case of a wide open pneumothorax, the otherwise regularly occurring mediastinal flutter and the dangerous shifting of the heart. He shows that the efficacy of Graf's method of thoracoplasty is due to the preliminary operation, the resection of the first three ribs, an intervention that results in a stiffening of the mediastinum, and he recommends the resection for other thoracic interventions that require a rigid mediastinum and for cases in which a preliminary operation is feasible, otherwise he induces rigidity by infiltration with the coagulable, sterile animal plasma preparation. The author briefly reviews the technique of mediastinography.

Treatment of Pancreatic Cysts—Von Redwitz treated three cases of pancreatic cysts. A woman, aged 39 complained of a feeling of pressure in the upper portion of the abdomen and also of a nodule which constantly increased in size. Examination revealed intense pressure pain below the left costal arch. Palpation disclosed a long tumor, the size of a child's head. The lower pole reached almost to the umbilicus. The surface of the tumor seemed to be smooth and its consistency was tense and elastic. The tumor was not moved by respiration or against its base, but the abdominal walls could be moved freely against it. The transverse colon was detectable below the tumor. Demarcation of the spleen was possible by percussion. The following conditions were considered possible: pancreatic tumor, pancreatic cyst, mesenteric cyst or retroperitoneal ganglioneuroma. Following examination of the blood, gastric contents and feces, and after several roentgenograms had been made, it was finally assumed that the patient had a pancreatic cyst, although all reactions indicating disorders of the pancreas were negative. The diagnosis was verified by operation. The difference between pseudocyst and genuine cyst is that the wall of the first has no epithelial covering while the wall of the second has. Pseudocysts are usually of traumatic origin and are the results of encapsulation of an exudate or a pancreatic sequestrum after injury or necrosis of the pancreas. Genuine cysts are probably due to retention or proliferation. The differentiation of pseudocysts and true cysts frequently requires histologic examination. The author considers surgical treatment the best. The function of the pancreas became abnormal following removal of the cyst from this patient. The carbohydrate metabolism of such patients should be kept under control.

Action Mechanism of Gastric Juice in Pernicious Anemia—Tochowicz condensed the gastric juice of hogs or of man in the vacuum at a temperature of 38 C., from which he prepared an acetone extract and, following neutralization and determination of sterility, injected it intramuscularly in doses of from 10 to 30 addisin units, one addisin unit being equivalent to the active principle contained in 100 cc. of the not condensed gastric juice. While this unit cannot be constant, since the quality of gastric juices varies, he thinks that, as long as the blood-forming factor in the stomach has not been identified, a more exact determination of the dose will be impossible. He employed this extract of the gastric juice with success in two cases of pernicious anemia. Reticulocytosis was

noticeable only after an adequate amount of the extract had been administered (35 and 30 units, respectively) and it persisted for a long period. There was an increase in the leukocytes up to the normal and a percental reduction of the lymphocytes in favor of the eosinophil and neutrophil granulocytes and the simultaneous disappearance of the signs of degeneration and of pathologic regeneration. Then there was an increase in the number of megakaryocytes and of the blood platelets, a disappearance of the increased hemolysis of the erythrocytes and an increase in the cholesterol content of the blood. During the first stage of the treatment there was a noticeable increase in the activity of the entire bone marrow system but later this activity subsided somewhat and reached a normal rate. Aside from the persistence of a few megakaryocytes there was a complete remission, following treatment with the extract of the gastric juice. The author observed also a reappearance of papillae on the lingual mucous membrane, but the gastric secretion was not influenced. Because of the same therapeutic results obtained with liver and with this extract of the gastric juice, the author is convinced of the identity of the antianemic principle in the two cases. He assumes that the active principle is produced in the stomach and that the liver stores it but also releases it as it is required by the organism. The importance of this method lies in the fact that a single injection of an adequate dose is capable of producing a complete remission and maintaining it for perhaps several months.

Castle's Principle in Pernicious Anemia—Braun duplicated Castle's method of treatment in two cases of pernicious anemia and studied its mode of action on the bone marrow. In the first patient he let 150 cc of gastric juice from a hog act on 250 Gm of raw beef for one hour at 37 C. Then the juice was extracted (from 80 to 100 cc) and given to the patient by mouth. This procedure was repeated daily for thirty-two days. The author describes the results. The second case was treated similarly except that gastric juice from healthy human subjects was employed. The treatment was continued for forty-three days. The results were similar in the two cases and tallied with those obtained with stomach extract. The author concludes that the hormone which is active in pernicious anemia is produced by the gastric and duodenal mucous membrane of normal persons. Then it is colloid chemically combined with the administered protein and, following that, it is absorbed by the intestinal mucous membrane. In the liver, in the dried hog stomach, in the liver extract and in Castle's antianemic factor the hormone is bound to a protein fraction. This combination modifies the biologic and physicochemical properties of the therapeutic factors.

Diagnostic Mistakes in Gynecology—Kolde lays down rules to be observed in gynecologic examinations. He stresses that bladder and rectum should be empty and advises that the bladder be evacuated by means of the catheter to obtain urine for examination. Since rectal examination is absolutely necessary for a complete gynecologic examination, the rectum should be empty. The author stresses that bleeding should not be an excuse for postponement of a gynecologic examination. It is important to determine the etiology of leukorrhea. A watery, profuse leukorrhea, together with rare but severe menstruation, may indicate tuberculosis of the uterus, but a definite diagnosis can be made only on the basis of exploratory curettage, an intervention that requires great caution, since it may bring on an exacerbation of the process. A condition in which an erroneous diagnosis is likely is senile colpitis, in which eczema-like exfoliations and withering take place, changes that may be mistaken for cancer. Erroneous diagnoses are most frequent in case of erosions of the uterine cervix but if exploratory excision is resorted to they can generally be avoided.

Ulcerations in the vagina may be caused by pressure from pessaries and other devices or may be the result of injuries resulting from measures to induce abortion. In case of the simultaneous appearance of several vaginal ulcerations, the physician must consider whether they are a manifestation of *ulcera mollia*, of acute ulcer or of syphilis. The diagnosis of prolapse or other positional anomalies of the genitalia must be made with great caution, as they may be simulated by other disorders, for instance, vaginal prolapse by a cyst of the vaginal wall and ante flexion of the uterus by a myoma nodule of the fundus. After discussing the diagnosis of normal and pathologic frequency, the author stresses once more the factors that are important in exploratory curettage. He shows that it is advisable to make the intervention under anesthesia and emphasizes that the microscopic examination of the curettage material should never be neglected. Polyps removed from the genitalia should likewise be carefully examined. In case of backache, which is a frequent symptom of gynecologic disorders, not only should the pelvic organs be examined but the patient should be submitted to a thorough general examination. In chronic irritation of the appendix, the uterine adnexa are often involved and the appendectomy must consider the gynecologic rather than the purely surgical implications.

Acetylene Insufflation of Subarachnoidal Space in Meningitis.—In 1928 when Zeller first reported his method for the treatment of meningitis he stressed two points (1) the thorough removal of the infectious cerebrospinal fluid and (2) the rapid refilling of the spaces with fresh, nontoxic cerebrospinal fluid. To counteract the danger produced by the sudden reduction in pressure he decided to fill the subarachnoid space and the ventricles with gas and he chose purified acetylene which, because of its high solubility (thirty-three times as great as oxygen), eliminates the danger of gas embolism. He did not hesitate to remove all the cerebrospinal fluid. To effect a more rapid renewal of the cerebrospinal fluid, he resorted to Bier's cervical stasis repeated three times daily. In cases in which the cerebrospinal fluid contained thick pus the author resorted to the intravenous infusion of a 0.2 per cent solution of sodium chloride. By lumbar puncture a considerable amount of spinal fluid is withdrawn and, when the pressure has been somewhat relieved, gas is introduced under a pressure of 40 cm of water. The escape of numerous gas bubbles from the trocar indicates that all the fluid has been removed. He tried to utilize the bactericidal power of ether vapors by having the acetylene gas pass through a bottle partly filled with ether. Provided the temperature of the ether does not exceed 22 C excessive dosage does not have to be feared. The author thinks that in cases in which access to the cerebral subarachnoidal space is not possible by the usual method the orbital puncture, the ventricular puncture or puncture of the corpus callosum may eventually be resorted to. However, the suboccipital puncture is less dangerous in cases of partial or total spinal blockage. He reviews the results obtained in various forms of meningitis and thinks that his method will cure some cases that would otherwise be hopeless.

Treatment of Meningitis by Zeller's Method.—Jauerneck describes his experiences with Zeller's acetylene insufflation in thirty-six cases of meningitis of which fifteen went on to recovery. He stresses the necessity of early treatment. Several hours delay may destroy all prospects of recovery. He is convinced that the dangers of the method are slight. With the exception of mild symptoms of collapse he never observed deleterious effects. He admits that Zeller's method is only one aspect of meningitis therapy. However, he thinks that it might save some patients who otherwise would be incurable.

Rapid Determination of Sedimentation Speed.—Holzapfel employs a centrifuge and the well known Linzenmeier tubes, which, however, should have millimeter graduations. The tubes, containing 0.2 cc of a 5 per cent solution of sodium citrate and 0.8 cc of blood, are centrifuged for a minute at 3,500 or 3,600 revolutions. Then the clearly defined column of serum is measured. The author determined in numerous experiments that values of from 16 to 20 mm. are not yet accelerated, while values of over 20 are accelerated and those of less than 16 are retarded. The lowest value that he determined with this method was 8 mm and the highest 36 mm. The author shows a table in which the values, according to Linzenmeier, are compared with those obtained in the centrifuge. He concludes that the centrifuge method is advantageous in polyclinics and similar institutes where immediate decisions are necessary.

Effect of Postencephalitic Parkinsonism on Offspring.—Hoff and Wieser observed several children with cerebral disturbances whose fathers had postencephalitic parkinsonism. Procreation had taken place after the fathers had acquired epidemic encephalitis. They give the histories of three children, of whom all had paretic disorders of the extremities two were idiotic and one manifested choreal restlessness and a tendency to sexual delinquency. Since it is known that in the chronic stage of epidemic encephalitis the region of the third ventricle and of the hypothalamus is damaged, the authors studied the effect of an artificially induced impairment of this region on the offspring of mice. Experiments on male animals revealed that severe damage of the thalamic-hypothalamic region completely destroyed the procreative capacity, although the genitalia showed no changes. After a less severe impairment the offspring could not be carried to term or were not viable, while in case of slight damage the offspring, although viable, nevertheless showed permanent or temporary disturbances. This impairment of the offspring was produced only by damage to the thalamic-hypothalamic region, for injuries produced in other parts of the brain, although they were followed by severe neurologic disturbances in the animals so treated, did not result in an impairment of their offspring, which were begotten after the animals had had some time to recuperate. In spite of the fact that women with postencephalitic parkinsonism were not known to have defective offspring, the authors made experiments on female animals. They gained the impression that the impairment of the thalamic-hypothalamic region of female animals also has a deleterious effect on the offspring. They believe that, since a sterile impairment of the brain of animals produced in the offspring effects similar to those following encephalitis in man the secondary changes in the hypothalamic region and not the infection (encephalitis) as such cause the impairment of the offspring after encephalitis.

Internal Drainage of Pancreatic Cysts.—Vecchi differentiates between pseudocysts and true cysts of the pancreas and discusses the treatment. In true cysts complete extirpation of

the cystic wall is advisable. In pseudocysts this treatment is not feasible because of the extent of the cystic sac, its close connections with other abdominal organs and the absence of a true cystic wall that might be easily detached. The best treatment of the pseudocysts is the suturing of the cystic wall into the peritoneum and subsequent opening of the cyst (marsupialization). This method produces favorable results in many cases, but occasionally there develops a fistula, which may persist for a long time. Various measures have been employed to remove these fistulas, but some of the surgical ones are not without danger, while in others, although they are more effective, the technique is rather difficult. He mentions implantation into the stomach, the intestine or the gallbladder. It seemed desirable in some cases of pseudocysts to dispense with marsupialization and produce at once a connection of the cyst with a hollow organ and thus effect internal drainage. He describes a case in which, following evacuation of the cystic fluid he made a direct connection between the cyst and the anterior wall of the stomach, near the large curvature. The anastomosis was secured by two Gersuny wicks. Sixteen days later, these drainage wicks were removed from the anastomosis. At a roentgenoscopy several weeks later, it was impossible to detect a connection between stomach and pancreatic cyst. Examination several months later revealed that the patient was entirely free from complaints and that she had gained weight. The author concludes that internal drainage deserves consideration in the treatment of pseudocysts of the pancreas; however, it is necessary to give attention to the danger of reflux of gastric, intestinal or biliary contents. He emphasizes that the complications likely to be caused by reflux from the respective organ are essentially different from those found in cases of acute necrosis of the pancreas. In the choice of the selection of the organ to be used for anastomosis the location of the cyst and the technical possibilities must guide the surgeon.

Gonorrhea as an Allergic Process—Engel and Vigham report studies in which they show that, by means of a gonococcus toxin, a specific gonorrhoeal allergy can be demonstrated. They show that the intradermally demonstrable allergy is a true bacterial allergy, for the passive transmission experiment of Prausnitz and Küstner succeeded. The two stage intradermal reaction results in manifestations of local immunity in the skin as an indicator of an excess of antibodies. This excess appears independent of the maturation period that is observed in serum disease and in the nine-day exanthem, however, it is dependent on the reduction of the gonococci in the foci of the disease. This observation represents an essential modification of the two-stage tuberculin reaction. In view of the factors mentioned, gonorrhea may be considered a disease that permits the observation of bacterial allergic processes and with this the determination of biologic standards also applicable to tuberculosis, for (1) a specific antigen is present, (2) the direct microscopic demonstration of micro-organisms is nearly always possible, and (3) the bacteria are removed entirely from the body when cure is established.

Studies on Behavior of Serum Protein Bodies by Means of Weltmann's Reaction. J. Kretz and Olga Kudlac—p. 590

Renal Changes in Bence-Jones Proteinuria—Randerath aims at determining whether the renal changes that exist in case of elimination of Bence-Jones protein bodies are to be differentiated from the nephroses (Bohnenkamp, Ehrlich) and

whether, as Ehrlich suggested, the Bence-Jones kidney represents a particular (the fourth) type within the group designated as Bright's disease. He reaches the conclusion that the giant cell formations in the tube casts, on which Ehrlich had put especial emphasis, are neither characteristic for a certain type of nephrosis nor justify the differentiation of a fourth type of Bright's disease. On the contrary, his studies demonstrated that the formations considered by Ehrlich as the basis of hydronephrosis are really the results of prolonged and severe elimination of protein and thus represent late manifestations in the course of chronic nephroses, and that they may appear also in the course of diffuse glomerular nephritides, particularly in those with nephrotic aspects. For this reason the author adheres to the classification that groups the Bence-Jones kidney with the nephroses, with the reservation that, just as in other nephroses he doubts that a primary "degenerative" process takes place in the renal parenchyma in Bence-Jones nephrosis. He rather assumes, at least for the onset of the renal changes characteristic for the Bence-Jones proteinuria, a process that is to be classified with the storage nephroses.

Hyperproteinemia—Bürkel demonstrates that in diffuse disturbances of the bone marrow, such as pernicious anemia, leukemia and more localized disease of the bone marrow (carcinoma metastases), the maximum and minimum values of the protein content of the blood serum generally do not deviate greatly from the normal values and that the averages remain within normal limits. Of all the disorders of the bone marrow, only myeloma presents the symptom of hyperproteinemia, and not even all cases of myeloma manifest this symptom. However, it must not be overlooked that, histologically considered, myeloma is not a uniform condition, for it may consist of various types of cells, of myelocytic, myeloblastic and lymphocytic elements and of structures resembling plasma cells. Moreover, there are myelomas that consist of cells resembling erythroblasts. The myeloma described by the author consisted of giant cells of the bone marrow (megakaryocytes) and thus it may be grouped genetically as belonging to the myeloid system. Moreover, megakaryocytes were detected in liver and spleen which is a further indication that in this case there existed a disturbance of the myeloid system. The author assumes that hyperproteinemia is perhaps a specific symptom of those myelomas that originate in the so-called myeloid cells and also of other disturbances that originate in the myeloid portion of the bone marrow.

Asbestosis and Pulmonary Tuberculosis—According to Martz, asbestosis develops as a rule from five to fifteen years after the beginning of the inhalation of asbestos dust. Its first symptoms are shortness of breath and coughing with expectoration. Later there are added pallor, cyanosis, palpitation of the heart, loss of appetite and of weight and piercing pains during breathing. In advanced cases, dyspnea and cyanosis predominate and death is usually caused by cardiac insufficiency. In the beginning stages clinical examination reveals hardly any pulmonary changes, but later a diminution in the resonance is perceptible over the lower parts of the lung and dry and crackling sounds are heard over the basal portions. In the roentgenogram, three stages may be distinguished. During the first stage there is a greater density in the hilus shadows, the movement of the diaphragm is reduced and the lungs show more reticular and honeycombed outlines. The second stage is characterized by the appearance of numerous fine focal shadows, primarily in the lower portions of the lung. During the third stage the diaphragm is immobile, the outlines of heart and

diaphragm are no longer sharply differentiable and the lower and partly also the middle fields are clouded by numerous fine focal shadows, or the shadow may be homogeneous. Following a description of the necroptic aspects of the lungs of patients with asbestosis, and of the development of the asbestos bodies, also called "curious bodies," the author discusses the concurrence of asbestosis with pulmonary tuberculosis. He reports the history of a woman, aged 30, who from the age of 17 to 22 worked in an asbestos factory. During this time she had no complaints, but six years later she resumed work in the asbestos factory for ten months and the disorder appeared suddenly. He assumes that the renewed inhalation of asbestos dust may have activated a tuberculosis and that this in turn contributed to a more rapid manifestation of the asbestosis. He concludes that the prognosis is unfavorable in case of a concurrence of asbestosis and tuberculosis. In the case reported treatment for thirteen weeks in a sanatorium was without beneficial effects.

Erythema Exudativum Multiforme and Tuberculosis—Mayrhofer reports observations that indicate a relationship between the two disorders. He calls attention to a case in which the recurrent attacks of erythema exudativum multiforme did not cease until tuberculin treatment was instituted. In another case there was erythema nodosum, erythema exudativum multiforme and a rudimentary polyserositis. Because of the similarity of disturbances of the serous membranes that accompany erythema nodosum, erythema exudativum multiforme and so-called articular rheumatism to the true tuberculous serositis and because of the detection of tubercle bacilli in the blood during acute polyarthritis (Löwenstein, Busson and Popper), it appears that the rheumatic genesis of polyarthritis as well as of erythema exudativum multiforme and erythema nodosum, may be doubted. The author believes that a relationship to tuberculosis is highly probable, at least in a certain group of cases of erythema exudativum multiforme.

Intrapleural Calcium Therapy in Pneumothorax Exudates—Kriech says that the intramuscular injection of calcium helps to prevent exudate complications but that its results are not so satisfactory once the exudate formation has set in. He resorted to the direct intrapleural application of calcium. At the exploratory puncture, when the necessary quantity has been withdrawn for purposes of examination, he mixes in the syringe from 5 to 10 cc of a 10 per cent solution of calcium gluconate with the exudate and injects it. In many instances this measure arrests the exudation. Neither the fever nor the exudate increases further, and pulse and temperature quite often become reduced. However, after one or two days there frequently is a renewed increase. Then the puncture is repeated, some fluid is withdrawn and from 10 to 20 cc of calcium gluconate is introduced. After that there generally is an improvement and within from ten to twenty days complete resorption of the exudate takes place. During this time the patients are usually bandaged twice daily, but no other treatment is employed. A refilling of the pneumothorax is as a rule unnecessary, since the air is absorbed rather slowly during this time, and within three weeks the complication has generally passed, provided the exudate is sterile. The author stresses as an especial advantage of this form of calcium therapy that the subsequent development of adhesions is slight and that it prevents plastic pleurisy.

Reactivity of Muscles of Uterus to Solutions of Pituitary and to Epinephrine Under Influence of Hormone Preparations P. I. Fomina—p. 91

Influence of Female Sex Hormones on Carbohydrate Metabolism—Lehwirth studied the influence exerted by various female sex hormones on the carbohydrate metabolism of sexually mature female rabbits. The experiments were made with the gonadotropic hormone of the anterior hypophysis, with the fat-soluble follicular hormone with the corpus luteum

hormone and with the combination of the follicular hormone and the corpus luteum hormone. Prolonged treatment with the gonadotropic hormone of the anterior hypophysis resulted in a slight reduction of the sugar content of the blood. In the acute experiment (ten hours) the sugar content did not decrease after the first tolerance test with the hypophyseal hormone, but it did decrease after a longer preliminary treatment with the hormone. Already the first tolerance test with the fat-soluble follicular hormone or with the corpus luteum hormone resulted in a reduction of the blood sugar in the ten hour experiment. This reduction did not increase after prolonged administration of these hormones. Preliminary treatment with estrogenic preparations abolished the blood sugar reducing effect of the corpus luteum hormone. Studies on the modification of the carbohydrate tolerance, following preliminary treatment with the estrogenic substances mentioned, revealed that all these hormones weakened the glycemic reaction produced by the oral dextrose tolerance test.

Endometriosis of Urinary Bladder F. Settergren—p. 571

Diagnosis by Arthrography of Lesions of Meniscus—Lagergren reports his investigations with roentgenography of the knee joint, utilizing 20 cc of 17.5 per cent diodrast. With this opaque substance and by a simple technic he was able to demonstrate meniscal injuries in clinically uncertain cases. It was also possible to give a detailed description of the type and extent of the damage proved on arthrotomy. To get a good result it is important to take the roentgenograms of the knee in an oblique direction, as thereby a relatively free projection of the different parts of the menisci can be obtained. The effect of the opaque substance on the joint was studied. The author examined the cytologic conditions of the synovial fluid before and after the injection of the opaque substance and also tested the albumin and iodine contents of the synovia. In a number of cases in which operation was performed twenty-four hours after arthrography, a portion of the capsule was excised for microscopic examination. He emphasizes the difficulties encountered in the proper evaluation of the condition of the lateral meniscus.

*Silicosis in Porcelain Workers Seen from Roentgenologic and Some Clinical Points of View P. F. Møller—p. 1395

Preliminary Experiments with Addition of Diet Rich in Vitamins for Patients with Lupus Vulgaris S. Lomboli—p. 1403

Silicosis in Porcelain Workers—Møller says that roentgen examination of 828 porcelain workers revealed silicosis in 361 or 45.2 per cent, 213 of these being in the second stage or beyond. The silicosis was a slowly but steadily progressive form of comparatively benign peribronchial-perivascular-nodose type with tendency to early interstitial changes. Of the workers employed for a period of from twenty-six to thirty years, 58 per cent had silicosis of those employed for fifty years 100 per cent had silicosis. Although the men and women were with few exceptions capable of work at the time of examination it was found that the morbidity among the workers having silicosis was high, the tendency to disturbances of the respiratory tract was greater than in those without silicosis, and half of the deaths were caused by respiratory disorders. The investigations further showed that persons with silicosis are also exposed to other dangers, namely, spontaneous pneumothorax and cardiac degeneration, even at an early stage of the disorder. Complication with tuberculosis was comparatively rare and grave cases of tuberculosis were not seen. Complication with emphysema was extraordinarily frequent.

HEMOGLOBIN REGENERATION AS INFLUENCED BY DIET AND OTHER FACTORS

NOBEL PRIZE LECTURE

G H WHIPPLE, M D
ROCHESTER, N Y

Experiments usually have a past history or a genealogical sequence, and it may be appropriate at this time to review the genealogy of the liver diet experiments in anemia due to loss of blood in dogs. With Dr Sperry in 1908 we¹ took up a study of the liver injury produced by chloroform anesthesia, giving particular attention to the regeneration of the liver cells to repair this injury. Icterus invariably is present in dogs with liver injury of this character and this condition was studied further. With Dr King we² studied obstructive jaundice and found that the bile pigments were absorbed from the liver into the blood capillaries direct rather than by way of the lymphatics. With Dr Hooper in 1912 we³ began a systematic study of bile pigment production in the body as influenced by the Eck fistula and finally⁴ were able to show that hemoglobin could be rapidly changed into bile pigment within the circulation of the head and thorax the liver being completely excluded, also that hemoglobin could be rapidly changed to bile pigment within the pleural or peritoneal cavities.

After leaving Baltimore in 1914 to work at the University of California, Dr Hooper and I⁵ took up a careful study of bile pigment metabolism by means of bile fistulas in dogs and investigated the effect of diet on the output of bile pigment. As these studies were continued and extended to include bile fistulas combined with splenectomy and the Eck fistula,⁶ it became apparent that we could not understand completely the story of bile pigment metabolism without more knowledge about the construction of blood hemoglobin in the body. Blood hemoglobin is a most important precursor of bile pigment, and it was necessary to understand what factors influenced the building of new hemoglobin in the dogs.

For this reason we produced simple anemia in dogs by means of the withdrawal of blood and in short experiments followed the curve of hemoglobin regeneration back to normal. These experiments with Dr Hooper⁹ were begun in 1917, and it was found at once that diet had a significant influence on this type of blood regeneration. Because of our interest in liver function and injury,¹⁰ we soon began testing liver as one of the diet factors and could readily demonstrate that it had a powerful effect on hemoglobin regeneration.¹¹ These short anemia experiments were relatively crude and gave at best qualitative values for the various diet factors.

After transfer of the anemia colony of dogs from San Francisco to Rochester, N Y, in 1923, Dr Frieda Rabschait-Robbins and I¹² began to use a different type of anemia. Dogs were bled by aspiration from the jugular vein and gradually reduced from a normal hemoglobin level of 140-150 per cent to about one-third normal, or 40-50 per cent, and this anemia level was maintained a constant for indefinite periods by suitable removal of new-formed hemoglobin. The potency of the diet factor was then accurately measured as grams of hemoglobin removed to preserve the constant anemia level. The stimulus presumably was maximal and uniform, and the reaction of a given dog to a diet factor was shown to be uniform when repeated time after time.

Much effort and time were spent in devising a basal ration that is adequate for health and maintenance during these long anemia periods, lasting throughout the entire life of the dog (from five to eight years). At the same time, salmon bread (table 1)¹³ permits of minimal new hemoglobin regeneration and therefore gives a low base line hemoglobin output from which to measure the increased output due to liver, kidney, gizzard or other favorable diet factors.

From table 2 it is obvious that liver¹³ again stands out as the most potent diet factor. Kidney¹⁴ is a close second. Gizzard, spleen and pancreas also rate high as factors that favor abundant new hemoglobin production under these standard anemia conditions. Gradually various diet factors were standardized, and this information was placed at the disposal of physicians who were concerned with the therapeutic treatment of human anemias. Iron¹⁵ was found to be the most potent inorganic element.

Pernicious anemia examined from the point of view of the pathologist¹⁶ was described in 1921 as a disease

in which all pigment factors were present in the body in large excess but with a scarcity of stroma building material or an abnormality of stroma building cells. This fits quite closely with the modern conception of this interesting disease as developed from the important observations of Castle.¹⁷ When the true factor is isolated I shall be surprised if it does not have to do with the stroma, but it may be related to the globin fabrication.

* McCollum and Simmonds salt mixture with ferric citrate omitted

Hemoglobin utilization in anemia was studied in considerable detail. It was found that the anemic dog can conserve for new hemoglobin production about 100 per cent of injected hemoglobin¹⁸ whether given intravenously or intraperitoneally. Muscle hemoglobin was included in this study and there is a probability that some of the injected muscle hemoglobin is also used in this emergency to form new blood hemoglobin.¹⁸ Certain digests of blood hemoglobin when given intravenously will be utilized to about 40 per cent to build new hemoglobin in the anemic dog.¹⁸ Foreign hemoglobins (goose and sheep) are also readily utilized¹⁹ when given intravenously to the anemic animal and nearly 100 per cent conservation was observed. Hemoglobin fed by mouth is poorly digested and we observe

tion in this type of experimental anemia and represents only 3 per cent of the whole liver weight.

Anemic dogs produce more new hemoglobin during a fast than during periods of the basal diet, and this phenomenon has received much study with the hope that information relating to the internal metabolism of hemoglobin may be acquired. When a standard anemic dog is fed only sugar plus iron, there will be a large output of new hemoglobin (100 Gm or more as a result of a two weeks fast). Obviously this new hemoglobin must be derived from the body protein, and the mechanism of this reaction has been investigated by Drs. Daft, Robschit-Robbins and Whipple.²² Nitrogen partition of the urinary nitrogen shows that during such periods there is a conspicuous decrease in the urea ammonia fraction that points to a conservation of nitrogenous intermediates which otherwise would appear as urinary nitrogen but under these circumstances are used to build new hemoglobin. The importance of this body reaction is obvious and it is being studied in considerable detail (table 3).

Human liver material obtained at autopsy has been studied recently²³ and its potency compared with stand

only about 10 to 15 per cent recovery as new formed hemoglobin in anemia.

Liver fractions and extracts have been studied²⁰ and the active principles for this type of anemia separated from the active principle of pernicious anemia²¹ as contained in the normal liver. The crude secondary anemia fraction²⁰ contains about 65 to 75 per cent of the potency of whole liver for new hemoglobin produc-

and animal liver material. If pig liver is rated as 100 per cent (our normal base line), any given type of human liver may be compared with this control by means of our standardized anemic dogs. In this way it was found that the human liver from young healthy adults gives average values of 160 per cent. Elderly persons with arteriosclerosis and degenerative changes will show values for liver tissue of 117 per cent as compared with the animal control of 100 per cent. Acute infections of course show swollen livers, and this increase in size may account for the "dilution" of the active principle, but the average value for this liver tissue is 117 per cent. Chronic infections give liver values that are practically normal (150 per cent). Cancer invasion of the liver reduces the values of the whole liver in proportion to the replacement by cancer tissue, which by itself appears to be inert. Liver cirrhosis is compatible with normal human values for the liver tissue, 164 per cent of the control animal liver, but when hepatic insufficiency supervenes these values drop markedly (48 per cent), or about one-third the human normal. Secondary anemia and leukemia show values somewhat below the human normal (125 per cent).

indicating a moderate depletion of these reserve factors within the liver, presumably due to blood loss

Pernicious and aplastic anemias show a definite heaping up of these potent factors within the liver tissue, which values run above 200 per cent. In aplastic anemia there is no formation of red cells, therefore the hemoglobin building material piles up in reserve. In pernicious anemia there is a lack of something so that the

marrow cannot produce the needed red cells, therefore the hemoglobin building material heaps up in the liver storehouse (tables 4 and 5)

Dogs with abnormal conditions are being included within the anemia colony and observations are accumulating to show in what measure splenectomy, the Eck fistula and the bile fistula may introduce factors having a bearing on the production of new hemoglobin under these standardized conditions. Acute and chronic infec-

tion, liver injury and chronic nephritis are also being observed in the anemia colony. The list of abnormal states is a long one and includes disease conditions developing spontaneously as well as acute conditions of purely experimental nature. New hemoglobin regeneration can be influenced by many of these disease conditions, but it would be premature at this time to attempt evaluation of these effects. It is an interesting field full of difficulties but also of promise for the future.

Amino acids deserve particular attention in this type of investigation and it should be possible to give certain amino acids intravenously and thereby influence hemo-

globin production in anemia. We are proceeding with a systematic investigation of amino acids as diet factors in our standard anemic dogs. It would be premature to make any statement about amino acids at this time, but certain amino acids do exert a definite influence on hemoglobin regeneration when added in moderate amounts to the basal ration. Phenylalanine, tyrosine and proline may be mentioned, but we have as yet no adequate data to establish any definite claim. The literature already contains too many claims for the potency of one or another amino acid in anemia, but the experimental data are wholly inadequate.

TABLE 5—Hemoglobin Production Factors in Human Liver

Diagnosis	Cases	Average Iron Content Mg per 100 Cc	Average Ratio of Human to Control per Cent
Normal	9	12	162
Normal ?	11	12	117
Acute infections	11		117
Chronic infections	19	13	149
Chronic passive congestion liver	6		94
Amyloid—fat liver	10		111
Cancer liver	8	15	75
Cirrhosis	20	9	104

Perfused anemia	8	51	218
Aplastic anemia	4	70	201
Secondary anemia	10	7	135
Leukemia	14	13	129

It is obvious to any student of anemia that a beginning has been made but our knowledge of pigment metabolism and hemoglobin regeneration is inadequate in every respect. This is a stimulating outlook for the numerous investigators in this field, and much progress in the near future may be confidently expected.

NUTRITION AND INFECTION

S. W. CLAUSEN, MD

ROCHESTER, N. Y.

The idea that a normal state of nutrition confers resistance to infection has long been held. Following the discovery of the accessory food elements, since 1900 an enormous amount of study has been devoted both to the defining of the various nutritional deficiencies and to a search for those food factors which might promote resistance. In this work, experiments with animals have been indispensable and have led to the solution of some of the clinical problems. It has been found that (1) outspoken deficiencies may lower resistance to infection, (2) increased feeding of such food elements as vitamin A to the normal animal may not increase resistance, (3) the results obtained with one species do not necessarily apply to another species, (4) very few studies have been made in animals receiving a diet only partially deficient, yet partial deficiency in man is far more frequent than total deficiency, (5) multiple deficiencies in man are frequent and may be important, and (6) very little attention has been paid to the production in animals of a chronic condition of reduced resistance, comparable to the condition that many clinicians believe exists in certain children.

Students of disease in childhood have described certain persisting constitutional conditions peculiar to groups of infants who are especially liable to respira-

From the Department of Pediatrics of the University of Rochester School of Medicine and Dentistry.

tory infections Czerny¹ described an exudative diathesis characterized by irregularity in gain of weight, enlargement of the lymph nodes, frequent catarrhal inflammations of the nose throat and bronchi, eosinophilia, eczema and asthma. He supposed that a diet rich in carbohydrate might favor the development of the diathesis and that one rich in fat might hinder its development. At that time the concept of allergy was not known. Stoeltzner² and Senff³ have called atten-

TABLE 1—Decrease in Severity of Infection Among Infants After the Introduction of More Adequate Diets (After Nassau⁶)

tion to the rapid gain and loss in weight characteristic of many infants who are liable to severe infections, they term the constitutional peculiarity of these infants "hydrolability" and include among the causative factors prematurity, a preceding toxæmia, and faulty diets. It is asserted that diets rich in fat may correct hydrolability. Abels⁴ considered that scurvy might lead to a faulty reaction to infection and coined for this the term "dysergy."

While these ideas were developing in Germany, diets were in use that were inadequate in many particulars. Hoeckle⁵ emphasized the deficiency of their caloric content. Nassau⁶ (table 1) showed that in infants under his care in Berlin the mortality very greatly decreased after 1922, when feedings were introduced that were higher in caloric content, in fresh fruit juice and in vegetables. No change had occurred in the type of infant admitted, in the technic of isolation or in the hygienic routine. Table 1 also shows that mild infections were no less frequent than before and that infants under 6 months of age not frequently were severely infected.

That the sex of the infant may play a role is illustrated by data collected at the Strong Memorial Hospital, as shown in the accompanying chart. Below the age of 3 months boys were much more liable than girls to severe infections, and girls were more liable after 6 months. In the chart it is clearly shown that the ratio

of severe to mild infections reaches a striking maximum both for girls and for boys between the ages of 9 and 12 months. This observation is well known. The explanation is quite unknown. It is perhaps due to the loss of protection acquired from the mother and to the fact that the infant has not yet developed its own protective mechanism. I have attempted by a rather crude statistical method to ascertain whether or not this lowered resistance is due to an increased exposure to infection. For this purpose I have assumed that the source of virulent infection would be older children in the family, and I have attempted to correlate by the coefficient of contingency of Yule the presence of severe infection with the presence or absence of older children in the family. No such correlation was found. Also, the previous intake of abundant vitamin A in the form of cod liver oil is not well correlated with this maximum peak of occurrence of severe infection between 9 and 12 months, although, as will be shown later, it may be correlated with the tendency to severe infection throughout the period from 6 months to 24 months. It may therefore be concluded that a number of constitutional factors must be taken into account in any study of liability to severe infection, such as age, sex and allergy, and undoubtedly that constitutional states exist, which in the past have been called "diatheses," "hydrolability" or "dysergy," all characterized by liability to severe infection. It is also probably true that the diathesis is a state that develops gradually and is in part the result of dietary deficiencies of considerable previous duration, and that it is a state which tends to persist.

I shall now review briefly the more significant observations in the literature bearing on the loss of resistance to infection due to deficiency of the food elements.

Effect of sex and age on severity of infection during infancy: boys, heavy solid line; girls, heavy dotted line. Effect of bad nutrition and of exposure to older children indicated by the coefficient of contingency of Yule. Six hundred and eighty children under 3 years of age.

THE EFFECT OF LONG CONTINUED USE OF DIETS LOW IN CALORIC CONTENT

Gordon and Tarr⁷ observed that the majority of their tuberculous adult patients had for several years been accustomed to consuming diets containing as low as 1,400 calories a day, and in a few cases as low as 800 calories. The diet of tuberculous children had not been so low in calories but had been of inferior quality. My own observations do not support the view that a

low caloric intake of itself predisposes infants to infection (table 2). The mean weight of 131 infants with otitis media and of fifty-nine infants with pneumonia lay considerably below the mean weight of healthy infants. This might suggest that undernutrition of itself predisposes to such infections. It seems more likely, however, that the loss of weight is a consequence of the infection. The mean weight of sixty-one infants admitted to the hospital for regulation of feeding but free of infection, was 81 per cent below the normal, and the difference between this weight and that of children with pneumonia and with otitis media was not of statistical significance.

EFFECT OF THE VITAMINS

Vitamin B—Pigeons suffering from polyneuritis lose their natural complete resistance to anthrax. This is probably due to a lowering of the body temperature or to starvation (Findlay,⁸ Corda⁹). Spontaneous or induced infection with *Bacillus Welchii* may occur in

TABLE 2—Undernutrition in Respiratory Infections (of Infants from Birth to Three Years)

Diagnosis	Number of Cases	Departure from Mean Normal Weight	Difference Between Weight of Infected Infants and Weight of Noninfected Infants
No infection	78	-8.1 ± 1.3%	—
Otitis media	131	-11.0 ± 1.0%	2.9 ± 2.1%
Pneumonia	59	-13.0 ± 1.3%	4.9 ± 1.9%

dogs partially deficient in vitamin B (Rose¹⁰). Women whose diets are deficient in vitamin B are liable to give birth to premature infants (Maurer and Tsai¹¹, Wills and Talpade¹²). No statements have been found dealing with liability to infection in beriberi or pellagra nor has any one recorded an attempt to prevent or treat infection in children with vitamin B.

Vitamin C—There is a large body of convincing evidence that guinea-pigs on diets partially or totally devoid of vitamin C are abnormally susceptible to infection with the streptococcus (Jackson and Moody¹³), the pneumococcus, *Staphylococcus aureus* (Findlay,⁸ Wamoscher¹⁴) and the tubercle bacillus (Bieling,¹⁵ McConkey and Smith¹⁶). Rinehart, Connor and Mettler¹⁷ have called attention to the resemblance between the lesions due to hemolytic streptococci in infected scorbutic guinea-pigs and rheumatic fever in man. However, Keith and Clayton¹⁸ in Rochester, Minn.,

have shown that the blood, urine and tonsils in rheumatic children contain normal quantities of vitamin C. Human infants with scurvy, according to Abels,⁴ are especially liable to severe infection. Meyer¹⁹ advocated the use of from 2 to 3 ounces (60 to 90 cc) of orange juice daily in the treatment of infants with infection. Orange juice, of course, contains many other active constituents than vitamin C, among them carotene, calcium, phosphate and potential alkali, it also appears to exercise an anti-infective influence in the rat, which needs no vitamin C (Hagedorn²⁰). Bloch²¹ believes that scorbutic infants are not unusually liable to infection or diarrhea. Adults with intestinal tuberculosis are said to be much improved by orange juice or tomato juice (McConkey²²). The synthesis of vitamin C within the past year will make available the pure material for use and will definitely settle some of the differences of opinion that exist.

Vitamin D—In much of the experimental work, the controls have been inadequate. Robertson²³ has reported on an extensive study which shows that the rachitic rat is unusually susceptible to paratyphoid bacilli fed by mouth, sunlight afforded better protection than did ultraviolet radiation from the quartz lamp or than did cod liver oil. Since these agents should have cured the rickets, it is difficult to agree that loss of resistance is due entirely to rickets. Rachitic rats, infected by intraperitoneal inoculation by Bradford and Boynton²⁴ were not more susceptible than normal controls. Ultraviolet irradiation does not confer protection on rats (Hardy and Chapman²⁵) or on mice in artificial epidemics of paratyphoid infection (Hill, Greenwood and Topley²⁶). The resistance of infants to colds and pneumonia is not increased by viosterol, or by irradiation with the carbon arc or mercury vapor quartz lamp (Barenberg, Friedman and Green²⁷, Barenberg and Lewis²⁸), and the tendency to repeated colds in adults cannot be prevented by ultraviolet irradiation (Doull, Hardy, Clark and Herman²⁹), nor do these agents cause healing of bone tuberculosis (Kramer, Grayzel and Shear³⁰) or of pulmonary tuberculosis (Kaminsky and Davidson³¹, Gordon and Tai,³² Scheurlen and Orlowitsch³²). Toxic doses of viosterol

may promote calcification of tubercles due to bovine infection in the guinea-pig but not those due to human tubercle bacilli (Spies³³). In a series of infants from 6 to 36 months old studied in the Strong Memorial Hospital, the presence of active rickets was found not to be correlated with the presence of respiratory infections (table 3). In fact rickets was only half as prevalent in children with mild infections as in those without infections. This is probably due to the fact that a certain number of infants are admitted to the hospital for the treatment of uncomplicated rickets. Children with a severe respiratory infection are found to have

TABLE 3—Correlation of Respiratory Infections with Rickets in Children from Six to Thirty-Six Months of Age *

* The coefficient of Yule K is low indicating a slight correlation between the presence of rickets and severe infection

rickets more frequently than those with mild infections but not so frequently as those without infections. Evidently rickets may create a handicap for an infant with a respiratory infection. This seemed to be especially true in a small series of cases of pertussis. I have been impressed with the frequent occurrence of tetany in severe cases of pertussis (table 4). In a number of infants suffering from infections not of the respiratory tract (most of them having dysentery, pyuria or pyoderma), rickets played no obvious role either as a predisposing factor or in aggravating the infection (table 5).

Vitamin A—McCullum³⁴ first called attention to the extensive spontaneous infections in rats with xerophthalmia, others have confirmed this work and shown that such infections do not depend on an associated

rickets and may be prevented either by purified vitamin A or by carotene (provitamin A) (Drummond,³⁵ Daniels and her associates,³⁶ Green and Mellanby³⁷). Rats deprived of vitamin A are also unusually susceptible to oral infection with certain strains of paratyphoid

bacilli (Orskov and Moltke,³⁸ Orskov and Lassen,³⁹ Lassen⁴⁰) and to intraperitoneal injections of an organism of the mucosus type that is harmless to normal rats (Bradford and Boynton²⁴). In a study of artificial epidemics, Webster and Pritchett⁴¹ found that a diet apparently adequate for growth and reproduction and not causing xerophthalmia was inferior to one richer in vitamin A in preventing infection, this work suggests that a partial deficiency may have existed.

Considerable difference of opinion exists in regard to the relationship of vitamin A deficiency in man and resistance to infection. Although the normal diet should provide ample amounts of this vitamin, the diet actually consumed in times of want may bring about a relative deficiency. Jeans⁴² has shown that 20 per cent of children in certain urban districts of Iowa may have a form of night blindness curable by cod liver oil and therefore undoubtedly due to lack of vitamin A. Spence⁴³ does not believe that xerophthalmia is associated with loss of resistance to infection. The administration of cod liver oil or carotene did not lessen the incidence or severity of infection in the infants observed by Barenberg and Lewis⁴⁴ or by Hess, Lewis and Barenberg.⁴⁵ However, very few of the infants observed by these authors had been seen by them until after the age of 6 months, and the earlier diet was not

stated. Suthiff, Place and Segool⁴⁶ administered cod liver oil to a large group of children with scarlet fever without lowering the incidence of otitis media. I⁴⁷ was unable to prevent the complications of scarlet fever by administering carotene, although it was absorbed. In this work and in that of Hess and his colleagues, it seemed likely that the patients were already receiving adequate amounts of vitamin A. It may therefore be concluded that amounts of vitamin A above the usual optimal amounts do not increase resistance to infection.

A number of authors have reported that a deficiency of vitamin A may lower resistance to infection. Bloch⁴⁸ found that infants with xerophthalmia were unusually susceptible to severe infection and to diarrhea and for a period of eight years after recovery from the condition had an unexpectedly high death rate. Green, Pindar, Davis and Mellanby⁴⁹ reported that the frequency of postpartum fever could be reduced by the administration of a concentrate containing vitamins A and D. This work has not been confirmed. Ellison⁵⁰ administered a concentrate of vitamin A in 600 alternate cases of measles, the mortality in the treated cases was 3.7 per cent, in controls it was 8.7 per cent, and in 4,978 cases of measles that were observed in London at the same time it was 8.1 per cent. It is possible that a relative deficiency of vitamin A was present in these children.

It is my opinion that the use of adequate diets before the onset of an infection is of more importance than the administration of vitamin A during an infection. I⁵¹ have found that children with scarlet fever which pursues a favorable course have at the onset a higher level of plasma carotinoids than those in whom severe complications develop (table 6). I have also found⁴⁷ that children who have a low level of plasma carotinoids are more liable to repeated respiratory infections. But a small group of children with abnormally high plasma carotinoids was also susceptible. Infants⁵² who had

TABLE 6—Carotene in Scarlet Fever. All Cases Mild at Onset. Determinations Within Three Days of Onset

received cod liver oil from at least the third month of life showed no superior resistance to infection until after the sixth month, but thereafter they appeared to be very much less subject to severe infection. Vegetables containing carotene, if begun at the sixth month, also appeared to influence favorably the course of an infection up until the end of the second year (table 7). The type of feeding during the first year of life had no demonstrable effect after the second year.

The previous diet in another group of 317 infants between birth and 36 months of age was studied with special reference to the intake of extra vitamin A. The diet was considered "good" in this respect when cod liver oil had been administered at least from the age of 3 months and vegetables from the age of 6 months. If, however, rickets had developed in spite of cod liver oil, it was inferred not only that the quantity of vitamin D had been insufficient but also that the quantity of vitamin A had not been sufficient. The infections were classified as mild and severe. The data as arranged in table 8 indicate that previous bad nutrition is more frequent in children whose infections are severe and that severe infections are twice as frequent in children whose previous diet has lacked additional vitamin A.

MECHANISM OF THE LOSS OF RESISTANCE TO INFECTION IN DIETARY DEFICIENCY

It is generally agreed that the ability to produce circulating antibodies is normal in dietary deficiencies (Muller,⁵³ Werkman,⁵⁴ Simola and Brunius,⁵⁵ Greene⁵⁶) but that the general resistance to toxins and poisons may be diminished (Werkman⁵⁷). In deficiency of vitamin A, the leukocytes are normal in animals (Turner and Loew⁵⁸) and in man (Hennessey⁵⁹). The protective reaction of the tissues may, however, be inadequate in dietary deficiency. In scor-

butic guinea-pigs the bone marrow does not show signs of reaction during an artificial infection (Findlay⁶). The metaplasia of specialized epithelium in deficiency of vitamin A is a sufficient explanation of spontaneous infections, for they do not occur before the metaplasia has taken place (Arons and van der Rijst,⁶⁰ Harris, Innes and Griffith⁶¹). The more severe course of infections due to oral or intraperitoneal inoculation is probably to be explained by the inability of the tissue phagocytes of the liver, spleen and bone marrow to hold and destroy bacteria. More study should be

SUMMARY

Loss of resistance to infection has been established by animal experiments in cases of deficiency of vitamins A and C, and with some degree of certainty in cases of deficiency of vitamin B. Clinical observations also indicate that loss of resistance to infection occurs in man with outspoken deficiency of vitamin A and probably of vitamin C. There is some indication but not yet certainty that animals with rickets are more susceptible to certain infections. Rachitic infants are no less resistant than nonrachitic infants to infections outside the respiratory tract, it is not yet certain that their resistance to respiratory infections in general is decreased by rickets, with the exception of pertussis, in which disease resistance is very much decreased.

There exists no evidence in experiments with animals or in clinical observation that the addition of any of the vitamins to the diet will increase the resistance to infection of the host when the host has already been consuming a normal diet. There is also no evidence that a good diet will decrease the number of infections during the first six months of life. There is some evidence that an adequate diet in the early months of life may decrease the severity of infections during the latter part of the first year and during the second year. There is little reason to believe that the administration of vitamins after the onset of an acute infection will exercise any benefit on resistance. Chronic infections have so far not been adequately observed with the exception of tuberculosis.

Beyond doubt a constitutional state exists in infants, characterized by the susceptibility to infection and a loss of resistance. This state tends to persist. Many factors besides diet contribute to this state: age, sex, heredity, allergy, prematurity and earlier severe illness. I believe that an early adequate diet, particularly one rich in vitamin A, tends to prevent the development of this condition.

Strong Memorial Hospital

ABSTRACT OF DISCUSSION

DR. JESSE R. GERSTLEY, Chicago. I want to raise a point that has been perplexing me during these last years. Has the quantity or the proportions of the diet any effect on the child's resistance to infection? Dr. Clausen has devoted himself largely to a study of the vitamins. For many years pediatricians have felt strongly that mixtures low in fat and high in sugar lead to two types of disturbance in the infant. First, the actual resistance to infection is diminished, second the nutritional reaction as expressed by the loss of weight is much more severe. In recent experimental work I have used mixtures of whole cow's milk with 12 per cent carbohydrate. It has seemed to me that babies receiving this feeding showed a diminished resistance to the usual ward infections and also lost more weight during such infection than did the babies on breast feeding. I am wondering whether this is the experience of other observers and if so whether they believe that the unfavorable results are due to the high carbohydrate per se or to the factor of simple overfeeding. It seems to me that the study of the elements of the diet and the effects of overfeeding on reaction to infection have not been made the object of sufficient study. May I ask Dr. Clausen whether he believes that the factors in the diet relating to resistance to infection are limited to the vitamins.

DR. S. W. CLAUSEN, Rochester, N. Y. I am sorry that no data exist in the literature in which a real study has been made of the subject Dr. Gerstley asks about. I think one of the earliest observations bearing on the subject of fat and resistance to infection is that of Vail in England who studied the dietaries of tuberculous patients and who found that fat tended to prevent tuberculosis. When one considers that fat

is the most expensive form of food, it is probable that those who are getting a high fat diet were living in better circumstances. Objections of this kind can be raised against many of the published clinical studies. In Budapest, about 1904 or 1905, the observation was made that babies who had been fed on sweetened condensed milk, which was low in fat and protein resisted infections very badly. As soon as they entered the hospital they would immediately lose a great deal of weight, and many of them developed pneumonia. No control studies were made.

EFFECT OF AUTOLYSIS ON POTENCY OF LIVER IN TREATMENT OF PERNICIOUS ANEMIA

WILLIAM B. CASTLE, MD
AND
MAURICE B. STRAUSS, MD
BOSTON

In 1928 one of us investigated the question of whether the hematopoietic activity of mammalian liver and kidney demonstrated in the treatment of pernicious anemia by Minot and Murphy¹ and by McCann² was due to processes occurring in these organs after the death of the animal. For technical reasons the experiments were carried out with the pulp of lambs' kidneys in which postmortem autolysis was prevented within two minutes after the death of the animals, by boiling the material for five minutes in acidified water at pH 5. The daily administration to each of two patients with pernicious anemia of about 200 Gm of such kidney pulp during periods of ten days indicated an unimpaired potency in comparison with that of identical amounts of material prepared in a similar fashion from lambs' kidneys purchased in the market. Because the results of the observations were entirely negative, they were not published.

In 1932 Herron and McElroy³ reported the results of observations "suggesting that autolysis markedly increases the potency of liver in the treatment of pernicious anemia." The following year the same investigators⁴ published their results obtained in the treatment of thirteen cases of pernicious anemia with autolyzed liver. An analysis of the data on which their conclusions are based does not, however, entirely support their statement that "the oral dosage requirement of autolyzed liver approaches the intramuscular requirement of other liver preparations." To justify this statement the enhancement of potency would have to be at least thirty fold,⁵ and maximal reticulocyte responses and increases in erythrocytes should have occurred from the daily oral administration of the autolysate from 10 Gm of liver.⁵

Based on the well recognized features of the reticulocyte response to the administration of a single massive dose of liver extract, their case 13⁴ must at once be discarded, because the data presented indicate that the

The expenses of this investigation were defrayed by a grant from the Milbank Fund of Harvard University.

reticulocyte peak of 38 per cent occurred on the day following the first dose of autolyzed liver. Such a reaction is unknown as a response to therapy given the previous day. In response to the administration within four days of material derived from 810 Gm of autolyzed liver, case 2 yielded a maximal reticulocyte response, as did case 7 after the administration within two days of material derived from 400 Gm of autolyzed liver. Cases 1, 3, 4, 5 and 6 showed distinctly submaximal numbers of reticulocytes at the peak of their rise in response to the administration within three days of material derived from 600, 750, 450, 400 and 600 Gm of autolyzed liver respectively.

Examination of the data of Herron and McEllroy for increases in erythrocytes during the initial period of thirty days of therapy demonstrates that the results are by no means maximal for patients initially with 3 million or less red blood cells per cubic millimeter. In comparable patients, according to Minot and Murphy,⁶ the expected increase in erythrocytes after thirty days of the feeding of about 200 Gm of liver daily is on the average about 1.9 million per cubic millimeter. The greatest increase in erythrocytes in the first thirty days of treatment of the six patients (1, 2, 3, 4, 5 and 9) with initial red blood cell counts of 3 million per cubic millimeter or less occurred in case 3 and amounted to about 1.7 million per cubic millimeter, but this patient was given a transfusion with 500 cc of blood and given two parenteral injections of liver extract No. 343 (N. N. R.) in addition to the daily ingestion of the autolyzed liver. The average increase in erythrocytes in five of the patients (1, 2, 3, 4 and 9) was only 0.92 million per cubic millimeter at the end of thirty days. After twenty-five days of treatment, patient 5 had fewer erythrocytes than at the start. However, three patients with initial red blood cell counts of over 3 million per cubic millimeter (10, 11 and 12) gained an average of over a million cells per cubic millimeter in thirty days.

It is certainly worth knowing, both from a scientific and from a practical point of view, whether autolysis actually increases the potency of liver. Since there is now available a commercial autolyzed liver product made according to Herron and McEllroy's directions, a sufficient amount of this material⁷ was purchased in the open market for a series of controlled clinical tests. The package literature states that each gram of the autolyzed liver product is derived from approximately 7 Gm of fresh liver and represents the antianemic potency of from 20 to 30 Gm of fresh liver. The method of testing involved making a comparison of the reticulocyte response produced by the daily administration of a uniform submaximal dose of the material to be assayed with the reticulocyte response obtained from a known source of active material similarly administered during an immediately succeeding period. If a second reticulocyte peak occurs under these conditions, it indicates that the potency of the known substance administered in the second period is greater than that of the unknown substance first administered.⁸

Three patients were given daily 10 Gm of the commercial autolyzed liver preparation derived from 70 Gm of liver and stated to have the antianemic potency of from 200 to 300 Gm of raw liver. As may be seen from the accompanying table, the red blood cells and

hemoglobin remained essentially unchanged in all three patients after ten days of such treatment. The reticulocytes rose to 62 per cent in case 1, a distinctly submaximal value at an initial red blood cell level of 1.95 million per cubic millimeter. During the next ten days, patient 1 received daily a commercial preparation of fraction G of Cohn, Minot, Alles and Salter,⁹ having the antianemic potency of 200 Gm of fresh liver.¹⁰ This material is actually derived from 300 Gm of liver, but approximately one third of the potency is lost in the process of manufacture.¹¹ By the sixth day the patient's reticulocytes had risen to 19.8 per cent. This observation clearly demonstrates that the autolysate from 70 Gm of liver did not have the potency of liver extract equivalent in effectiveness to 200 Gm of fresh liver. In the table data are given for only the actual period of administration of the substances named.

* Ten Gm of powder stated to be equivalent to from 200 to 300 Gm of liver.

† Total liquid, 257 cc derived from autolysis of 70 Gm of liver.

Patient 2 likewise received 10 Gm of "autolyzed liver concentrate" for ten days. No significant change in reticulocytes, red blood cells or hemoglobin occurred. During the next ten days this patient received daily 200 Gm of minced raw liver. The reticulocytes commenced to rise on the third day reaching a peak of 25.6 per cent on the eighth day. This observation corroborates that made on the first patient and fails to substantiate the claim that autolysis, as employed in the commercial process, increases the potency of the liver three or four fold.

Patient 3 received daily the same quantity of the autolyzed liver preparation as the first two patients.

10 Liver Extract Lilly, N. N. R.
11 Minot, G. R. and Castle, W. B. The Adequate Treatment of Anemia. *Ann. Int. Med.* 5: 159 (Aug.) 1931.

The reticulocytes reached a peak of 7 per cent on the eighth day. During the next twelve days this patient received 70 Gm of minced raw liver daily, which is the same amount of liver as that from which the "autolyzed liver concentrate" previously administered was stated to have been derived. On the eighth day of this treatment the reticulocytes reached a second peak of 12.8 per cent. This observation demonstrates no increase in potency of liver by the process of commercial autolysis. Actually a diminution in the amount of effective material had occurred, a fact that is in accord with many observations showing that any method of extraction of liver results in a loss of potent material.

The commercial product used in the foregoing tests was manufactured under a license to use U. S. patent application serial number 620301. With the claims for potency referred to, it is among the products accepted by the Council on Pharmacy and Chemistry of the American Medical Association. The commercial process may conceivably, however, have deviated from the one originally recorded by Herron and McElroy. Accordingly, we made an autolyzed liver preparation in exact accordance with the directions given by these workers.* This material, in amounts derived from 70 Gm of minced liver, was administered daily to patient 4 for ten days. A rise of reticulocytes to 7 per cent occurred on the eighth day. This patient was then given 70 Gm of minced raw liver daily. A second rise of reticulocytes, this time to a peak of 17 per cent occurred on the fourteenth day. This delayed response was probably caused by diarrhea produced by the raw liver when first administered. It demonstrates that an autolysate of liver made according to the directions of Herron and McElroy, far from having an increased potency, contains less active material than the original amount of raw liver.

CONCLUSIONS

1. The hematopoietic activity in pernicious anemia of kidney, and presumably of liver, does not depend on postmortem autolysis.

2. Experimental and commercial autolysates of liver, made according to the directions of Herron and McElroy, have less hematopoietic activity in the treatment of pernicious anemia than the amounts of liver from which they are derived.

The Most Severe Dancing Mania—In Erfurt in 1237 over one hundred children were taken with a dancing and raving disease, which again in many cases led to death and permanent tremors in the survivors. The most severe dancing mania began in 1374 in the wake of the Black Death at first at Arn-la-Chapelle soon in the Netherlands at Liege, Utrecht, Tongres and Coogne. Men, women and children lost all control, joined hands, and danced in the streets for hours until complete exhaustion caused them to fall to the ground. They shrieked, saw visions, and called upon God. The movement spread widely, and undoubtedly the numbers of the truly afflicted were enhanced by multitudes of the easily excited in a manner not unlike that observed in modern camp meetings and evangelistic gatherings. Yet there must have been a physical disease in many of the cases because throughout the accounts there is frequent reference to abdominal swelling and pain, for which the dancers bound their bellies with bandages. Many suffered from nausea, vomiting and prolonged stupor. The condition was sufficiently widespread and important to warrant a long dissertation by Paracelsus who tried to classify the malady into three subdivisions by a system not of sufficient modern importance to warrant review.—Zinsser, Hans. *Rats, Lice and History*. SURGICAL COMPLICATIONS IN THE TREATMENT OF GONORRHEA

INDICATIONS AND METHODS

ALBERT E. GOLDSTEIN, MD
BALTIMORE

In the preparation of this paper, an analysis was made of 1,000 consecutive cases treated for gonorrhea, the last 500 cases treated privately in my office and the last 500 cases treated in the free clinic at the Sinai Hospital being selected.

It was interesting to note that more complications of gonorrhea were observed among the private than among the free cases. This may be due to the fact that when a complication arises the patient is usually confined to bed and therefore the free case does not return to the clinic but is seen by another physician at home, or that the case was first seen by us in the complicated form. It was also observed that in the largest percentage of cases the complication occurred in the acute stage of gonorrhea.

I have not attempted in this study to bring forth the various methods of handling these complications but simply base my conclusions on the methods we have employed. These undoubtedly will differ in some instances with other investigators but as I am unbiased I am open to constructive criticism.

The complications that may occur during the course of treatment of gonorrhea differ, depending on whether the case is first seen as an acute or as a chronic one. There were almost three times as many acute cases of gonorrhea seen in the free clinic as were seen privately; yet the acute complications seen privately were many more than those seen in the clinic.

These 1,000 cases may be divided as in table 1.

The acute complications occurring while the patient was being treated for acute gonorrhea were observed in 209 cases out of 540 patients treated, or 38.5 per cent. The acute complications occurring in patients treated for chronic gonorrhea were found in thirty-two out of 460 cases, or 7 per cent.

Chronic complications seen in these 1,000 cases were observed in 358, or 35.8 per cent, of the cases. In many instances more than one complication was seen in the same patient and in most cases a chronic complication followed the subsidence of the acute one.

The complications that may occur during the course of treatment of gonorrhea are listed in table 2.

While some of the complications occur much more frequently than others, it has been observed that it is necessary to treat most of these complications surgically at some time or other, depending on the individual case. It is true that in most cases the complications were handled at first conservatively, and that surgery was employed after conservatism had failed. It is also quite true that many times surgery was necessary even after conservative treatment had been tried. In many cases in the series it was found that when the complication was treated early by surgical methods it was the most conservative form of treatment, especially in the acute complications. In other instances surgery was employed because of complicated sociological or economic conditions and in some instances was employed to avoid embarrassment.

From the Department of Genito-Urinary Surgery, Sinai Hospital. Read before the Section on Urology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 13, 1934.

It has been found that early surgery in the acute complications of gonorrhea resulted in quicker convalescence and was the most economical causing the patient to be totally disabled for the least number of days.

In this analysis it was found that surgery was employed in both the acute and the chronic cases but, as mentioned before, in considerably more cases in the acute stages than in the chronic stages. Opportunity was taken of performing surgery on every type of complication that might be amenable to surgery, both for the purposes of investigation and for the necessary relief in most cases. In some of the cases in which it was performed for investigative purposes it was noticed that no more beneficial results were obtained than if surgery had not been employed, such as prostatotomy in cases of chronic prostatitis.

Since most of the complications requiring surgery are acute cases or acute cases superimposed on a chronic case the indications are quite similar. The various conditions mentioned have symptoms in common when in the acute stage, such as pain, swelling, chills and fever, and urinary disturbances, such as frequency, painful urination, urgency, and sometimes urinary retention and urinary fistula. In a study of the blood it was found that there is some degree of leukocytosis present. Frequently a toxemia presented itself, especially when there was an overwhelming infection.

TABLE 1—Classification of One Thousand Cases

	Private Cases	Free Cases
Acute gonorrhea	143	89
Chronic gonorrhea	33	10

In this series of 1,000 cases treated, eighty-six, or 8.6 per cent, of the cases came to surgery, and operations were performed for the conditions shown in table 3. In this series no operation was done for perineal or urethrocutaneous fistula, sterility or pyonephrosis, but I have had the opportunity of performing, on previous occasions, operations for all these complicated conditions excepting for gonorrheal pyonephrosis.

Considering the conditions separately as to when surgery was indicated and the type of surgical procedure that was employed, it will be necessary, in order to understand the procedures, to consider each one separately.

EPIDIDYMITIS

Most of the cases of acute gonorrheal epididymitis, if permitted, will subside with the ordinary treatment of rest, support of the scrotum, and the application of ice. During the course of treatment the patient is usually uncomfortable and in most cases suffers a moderate or extreme amount of pain. It may be considered radical but I feel that, when the pain is increasing in severity and the infection is gradually involving more of the epididymis, open surgery is indicated, first to relieve the pain, which is relieved almost immediately, and secondly to preserve the patency of the epididymis and vas deferens if possible.

The production of pain is caused not by the presence of pus but by the presence of congestion and edema in the epididymis, during this pathologic process plus the presence of free fluid between the layers of the tunica vaginalis. It is rare that free pus is found in the epididymis in acute gonorrheal epididymitis. The usual procedure is to do an epididymotomy, by making numerous punctures in the epididymis throughout its

course, together with opening the tunica vaginalis and permitting the free fluid to escape. I also evert the sac by doing a Bottle operation on the tunica vaginalis. In operating on these patients, a careful examination is made of the epididymis. If it was observed that the pathologic process was very marked with a possibility that the lumen might be obliterated, or free pus found, or that it was a case of a recurrent acute epididymitis, an epididymectomy was performed.

Criticism undoubtedly will be made because of the latter procedure, but I have found that, when I did an epididymotomy in cases in which free pus was present, a recurrent epididymitis resulted. If the patient was

an unmarried or young married man, epididymotomy was always performed, but if the patient was one who had two or more children, an epididymectomy was performed, always with an explanation to the patient beforehand that the procedure might be advisable or necessary. Bilateral epididymectomy was never performed except when it was a bilateral recurrent condition in a married man with children.

In this study there were 175 cases, or 17.5 per cent, of epididymitis occurring during the course of treatment for gonorrhea, both acute and chronic. In 540 cases treated for acute gonorrhea, acute epididymitis developed in 143, or 26.4 per cent. In 460 cases treated for chronic gonorrhea, acute epididymitis developed in thirty-two, or 6.9 per cent.

Of the 175 patients with acute epididymitis, forty-four, or 25.1 per cent, came to operation. The others

either refused an operation, or the condition had subsided sufficiently in a few days to make it appear that an operation was not necessary. In the forty-four patients operated on, twelve, or 27.2 per cent, had an epididymotomy, and thirty-two, or 72.8 per cent, had an epididymectomy. Two patients had a bilateral epididymotomy and three patients had a bilateral epididymectomy.

Three of the twelve patients who had an epididymotomy performed developed a recurrence at some future date, resulting in subsequent epididymectomy.

In the thirty-two cases in which epididymectomy was performed, three presented free pus in the epididymis and twenty-eight, or 87.5 per cent, showed definite occlusion of the lumen when studied microscopically. In the thirty-two cases in which a unilateral

epididymectomy was performed, a subsequent epididymitis developed on the opposite side in four cases, none of which came to operation. In twelve cases in this group the patient became the father of a child on some subsequent date.

In the chronic stage of epididymitis, no operative procedure was employed excepting when the patient complained of a chronic pain or when I felt that it was a focus of infection. This was carried out in three cases.

ACUTE PROSTATITIS

During the course of treatment of acute gonorrheal urethritis, a sudden cessation of the urethral discharge is observed at times, followed by a burning, painful and frequent urination, associated with marked tenesmus. The patient suffers a discomfort in the rectum and on examination there is a sensation of warmth elicited over the prostate. The prostate is painful to pressure and is enlarged in several areas. In most instances these signs and symptoms are accompanied by chills and fever, with a general weakness and frequently nausea. The usual form of treatment is hot sitz baths, rest, forced fluids, opium and belladonna suppositories, and sometimes some instillations of 5 per cent mild silver protein into the posterior urethra are beneficial. Most of these cases subside under the usual form of treatment. I have taken two of the prolonged cases in which there was a great deal of pain and which failed to subside over a reasonable length of time and performed a prostatotomy through a perineal exposure by making numerous punctures in the prostate and draining these areas with rubber tissue drains for about one week. It is rare in these cases that free pus is found, but the reduction of the congestion and edema gives remarkable results. I feel that punctures in these cases will prevent a prostatic abscess in many instances. The two cases that were seen subsided promptly.

CHRONIC PROSTATITIS

When the condition became chronic, it did not lend itself to surgery. In the past two years two cases of chronic prostatitis became the subjects of surgical procedure. There are no definite indications for surgery of the prostate in the chronic gonorrheal stage. I have subjected two patients to prostatotomy, the same as when performed in the acute stage. As there were no definite indications for surgery excepting the chronicity of the condition, demonstrated by numerous pus cells with clumps in the prostatic secretion, this method was employed without any satisfactory results.

PROSTATIC ABSCESS

One of the most common complications resulting from gonorrhea requiring surgical intervention is a prostatic abscess. This occurs during the course of treatment for acute gonorrheal urethritis and as a rule occurs between the second and fourth weeks of treatment. There is probably no complication of gonorrhea excepting epididymitis that produces more discomfort and pain than a prostatic abscess. The early symptoms of these cases are chills and fever, painful, urgent and frequent urination, and often acute urinary retention. A rectal examination reveals a large, soft, boggy and painful prostate, which fluctuates.

The early cases were treated palliatively by rest, hot rectal douches, sitz baths, opium and belladonna suppositories and, when necessary, the introduction of catheters into the bladder. In the last five years, the method of handling this situation is to recommend early operation. I prefer whenever possible to per-

form a perineal section and after the rectovesical fascia has been stripped posteriorly to incise the prostate in several areas and drain these areas. Care is taken not to open the urethra or extend the incision into the bladder. I prefer not to place catheters in the bladder. If the patient has had an acute retention before the operation, I have found that in less than twenty-four hours after the operation he is again able to void and with considerably less discomfort. Only four cases of prostatic abscess came to operation. Large quantities of pus were discharged at the time of operation, giving the patient almost instant relief.

INGUINAL ADENITIS

The enlargement of the inguinal glands is usually not associated with gonorrhea. In the analysis of the cases I found that in one case during the course of treatment of acute gonorrhea the inguinal glands became enlarged and suppurated. There were no other lesions present on the penis to account for the unilateral infection. The presence of pain in this region and the fluctuation in the broken down glands are indications for incision. Opening and draining this area is sufficient to permit of healing.

PERIURETHRAL ABSCESS

The closure of one of the glands of Littre producing a swelling and lump in the penis is known as a periurethral abscess. This usually occurs early in the course of the disease, causing the patient quite a good deal of discomfort. In its early stage the patient usually complains of a lump on the penis which is painful and in many instances causes painful urination with obstruction to the flow of urine. There were nine such cases that came to operation.

Again palliative measures were often tried with a disappearance of the acute symptoms, but in most instances there is a chronic discharge present from the infection. Frequently the abscess ruptures in the urethra or at times ruptures externally, sometimes leaving a urinary fistula. If the condition, when seen demonstrates a definite abscess early incision and drainage externally will give quick relief. Care should be taken to avoid opening the urethra from the outside, otherwise a urinary fistula results. Should the abscess open into the urethra of its own accord, a small nodule forms, which is the result of fibrosis. This frequently causes a urethral discharge and is treated by massaging the gland over a sound.

ACUTE AND CHRONIC SEMINAL VESICULITIS

In the acute stage the symptoms are similar to prostatitis and practically always are associated with it. The same form of palliative treatment was employed in the acute stage as for acute prostatitis. Surgery has been employed in the acute stage in only two cases by incision and drainage of the seminal vesicles through a perineal exposure.

In the chronic stage, the condition was likewise associated with chronic prostatitis. Cases have come to surgery because of persistent urethral discharges, urinary discomforts, and the presence of pus in the urine. There were a few cases in which the patients had vague symptoms of joint pains. In three cases seminal vesiculotomy and in two seminal vesiculectomy were performed. In five cases the seminal vesicles were injected through the vas deferens.

The results obtained from the drainage of the seminal vesicles in the acute stage gave relief of the rectal discomfort of the pain and of the urinary discomforts.

The drainage of the seminal vesicles or the removal of them in the chronic stage showed no evidence of any special improvement. The injections of the vasa deferentia through the scrotum did not give the results that one might expect. All these cases had to be treated subsequently even though operation had been done. In those cases in which joint symptoms were present the operation gave relief for a short time.

ARTHRITIS ASSOCIATED WITH SEMINAL VESICULITIS

The presence of pain in a single joint during the course of treatment of gonorrhea is usually indicative of a gonorrheal arthritis. Other joints may eventually become involved but it appears that one joint at a time becomes affected. This joint usually becomes swollen and hot to the touch, motion is restricted and painful and the patient usually has a fever. The condition gets into the joint through the blood stream from the posterior urethra. Two cases of arthritis associated with seminal vesiculitis came to operation.

No case of acute gonorrheal arthritis came to operation, but two cases of supposedly chronic gonorrheal arthritis came to operation because of chronic pains in a joint. The seminal vesicles were indurated and contained many pus cells. The seminal vesicles were opened and drained through a perineal exposure relieving these two patients of their pain. Subsequent treatments in the way of massages of the seminal vesicles were continued.

PHIMOSIS AND PARAPHIMOSIS

In the presence of a discharge from the urethra, which very frequently becomes secondarily infected the undersurface of the prepuce becomes edematous and injected. As the process continues one finds marked swelling of the prepuce, so that it becomes impossible to retract the prepuce. In many cases the infection is kept up by the smegma, which normally is present around the corona. This condition is known as phimosis.

When the prepuce becomes edematous and swollen preventing the prepuce from being drawn over the glans penis, because of infection, the condition is known as paraphimosis.

As little surgery as is possible should be performed in these instances in the presence of infection. In many instances one is compelled to expose the glans penis, first to reduce the pain secondly to treat the gonorrheal infection, and thirdly because of the constriction of the prepuce around the glans. When these symptoms and signs are present and the prepuce cannot be drawn over the glans penis a dorsal slit should be performed. In the case of phimosis, when it is found impossible to treat the gonorrhea properly a dorsal slit should be performed, and the circumcision completed after the gonorrhea is treated.

URETHRAL STRICTURE

The presence of a long standing urethral discharge with infection in the glands of Littre frequently results in fibrosis and scar tissue with the result that a stricture of the urethra is formed. In this series of cases, most of the strictures were encountered at the bulbomembranous urethra. In some instances they have occurred in the membranous urethra. The early method of treatment was incising the stricture when it was found to be of a filiform type and would not dilate easily, or if there was a great deal of bleeding following a dilation. Incision of the stricture was never supposed to keep the stricture dilated, so that in

the past twelve years I have not resorted to incising the strictured area but to keep dilating it with filiforms and followers.

Whenever I was unable to pass a filiform by the stricture after numerous attempts or unable to keep the strictured area well dilated, I advised a retrograde operation. Three patients in this series submitted to such an operation with excellent results. In this operation a suprapubic cystotomy and a perineal exposure were made. Separate sounds were passed from the external meatus down the urethra and also one into the vesical orifice from the bladder. Both would become obstructed at the point of the stricture and would usually be palpated in the perineum. An incision was made over the tip end of each sound, the old urethra discarded at this point and a tube passed over the end of each sound. One end of the tube is passed up the urethra and out into the external meatus and the other through the internal vesical orifice and into the bladder. In this manner the tube is continuous throughout. There is no tissue sutured over the tube but left bare. This area is drained. In from eight to ten days epithelialization of this bare area has occurred over the tube and a new urethra has been formed. Dilation is then continued for a short while. I have never employed the methods of exposing the strictured area in the perineum after a dye has been given and the strictured area located. I likewise have never employed the method of resection of a portion of the urethra for stricture.

COWPERITIS

The occlusion of Cowper's ducts during the course of treatment for gonorrhea causes a swelling in the perineum, which fluctuates as a rule. This in turn causes urinary difficulties such as frequency, pain and burning on urination, with obstructive symptoms. As the condition progresses the swelling increases in size, and it is at this time that surgery is indicated. An incision into the abscess and drainage is the procedure. It usually subsides in a few days. Three cases came to operation.

URINARY EXTRAVASATION

While urinary extravasation never is directly the result of gonorrhea, it nevertheless is encountered at times following the treatment of the stricture of the urethra, or even without the treatment of the stricture. These patients are very ill when seen usually show evidence of extreme toxemia, and have chills and fever, leukocytosis, edema and areas of redness and fluctuation of the penis, scrotum, perineum, suprapubic regions and perirectal areas. This depends entirely on whether the extravasation is anterior or posterior to the triangular ligament. A history of gonorrhea is usually obtained together with the history that a stricture was present at one time or another.

Peculiarly enough, they frequently give a history of voiding fairly well. In spite of this, there is rupture of the urethra with extravasation of urine. The history may possibly be given that the stricture had been dilated. There should be no delay. When one is given a history of this kind with edema of one or all the areas mentioned and the presence of ecchymosis in these areas, open surgery should be resorted to. It should be radical, rapid and immediate. All areas involved should be incised and drained freely, all the abscess cavities being connected if possible. At the same time the urinary stream should be diverted by performing a suprapubic cystotomy.

The bladder is kept drained well until all the infection has subsided and a fair sized catheter can be passed into the urethra. In this series there was one such patient, who has made a complete recovery.

COMMENT AND CONCLUSIONS

In discussing the indications for surgery in the complicated gonorrheal case, one is impressed with the similarity of symptoms with the exception of the locality. In practically all conditions there is pain in a local area, rise in temperature sometimes preceded by a chill swelling of the particular area involved, and in all, excepting possibly epididymitis the presence of some urinary disturbance such as frequency, burning on urination, tenesmus, hematuria, and sometimes urinary retention. At times gastro-intestinal symptoms are present.

From an analysis of 1 000 cases treated for gonorrhea, it has been observed that complications were very prevalent. This entire series of 1,000 cases was not seen in the acute stages of gonorrhea. In many instances the case was first seen in a chronic stage or was seen first when this complication presented itself.

With a history of gonorrhea and the presence of one or all of the foregoing symptoms I feel that a competent urologist is justified in advocating surgical intervention. The length of time one should permit the patient to continue on with his symptoms hoping that nature will take its course is a personal issue. In my opinion, as soon as a complication is diagnosed and the patient is in distress the sooner surgery is performed the quicker the patient will be relieved.

Unfortunately, the largest percentage of cases treated for gonorrhea do not fall into the hands of surgical urologists; therefore when a complication arises the proper percentage of patients are not in a position to receive surgical intervention. As to the type of surgical intervention, it appears that in most cases it is a question of an abscess and therefore requires incision and drainage.

During the course of treatment for gonorrhea 710 complications developed in 418 or 41.8 per cent, of the patients of this series. Two hundred and forty-seven of the complications were very acute. Of the latter number 175 were cases of epididymitis. Eighty-six or 21.2 per cent, of the 418 patients developing complications or 8.6 per cent of all the patients treated, were operated on for a complication.

A further analysis of the complicated cases revealed a total disability of an average of eight days longer in the unoperated case together with considerably more pain over a longer period of time.

I am in hope that in the future the percentage of operations on complications of gonorrhea will be much higher. It is my belief that the appearance of a complication following the treatment of gonorrhea is best handled by open surgery in the largest percentage of cases. If surgery is employed early, there will be less suffering on the part of the patient, quicker convalescence and a considerable decrease in the number of subsequent chronic complications. I also feel that if surgery is applied early the morbidity will be decreased and the functional results better.

A major surgical procedure will be transformed into a simple minor procedure. Certainly many cases of one-sided sterility or, worse, the cases of bilateral sterility will be avoided if an early epididymotomy is performed rather than have the patient go through a great deal of suffering for several days and then subse-

quently be compelled to have an epididymotomy or epididymectomy, or, if surgery is not employed at all, to have the condition subside with the possibility of sterility or recurrence.

The same is true for periurethral and prostatic abscesses. If surgery should be employed early in acute prostatitis, I believe that many prostatic abscesses could be avoided.

Many chronic cases of urethral discharge are the results of procrastination until a periurethral or prostatic abscess ruptures into the urethra. An abscess of this kind in its early stages can be opened extra-urethrally so that the purulent discharge from the abscess will not come in contact with the mucous membrane of the urethra. Many cases of stricture of the urethra are directly the result of fibrosis that has taken place following the healing process of a ruptured sub-mucosal abscess into the urethra.

Epididymitis is the complication that is by far most encountered. In these cases there were considerably more epididymectomies performed than epididymotomies. The reasons for this were several: first, in most cases the complication had been present from five to ten days before the patient was seen or before the patient consented to an operation; second, there was free pus in the epididymis; third, the vas deferens was found to be obstructed; and, fourth, it occurred in patients who had two or more children and who were not particular whether they were sterile or not. If there is any chance or desire to retain the patency of the vas deferens or the epididymis, an epididymotomy must be performed early and is by far the operation of choice. It is advisable to inject the vas deferens to determine its patency before epididymectomy is performed.

Prostatic and periurethral abscesses should be incised and drained extra-urethrally as soon as the diagnosis is made. Cases of acute prostatitis should have a prostatotomy done early the same as one would do an epididymotomy early for epididymitis. Furthermore any abscess as a complication of gonorrhea should be opened and drained early to avoid chronic complications.

Surgical intervention in chronic undilatable urethral strictures has given good results. The results obtained in the chronic complications such as chronic prostatitis, seminal vesiculitis and others by treating them surgically have not been very satisfactory. All cases of urinary extravasation should receive immediate attention and always have suprapubic drainage.

Several of the complications not occurring frequently have been operated on but not in this series. In the cases of para-urethral duct infections, it is very essential to determine whether the infection in the urethra is being kept up by the infection in these ducts. If organisms or a discharge are observed coming from these ducts, treatment should be rendered. The injections or applications directly into the ducts have not given satisfactory results. I have obtained the best results by opening the ducts and uniting them with the urethra and then treating the infection as one.

Perineal fistulas the results of urethral strictures and abscesses present pictures of chronic purulent discharges and in many instances with urinary discharges. Dilations of the urethra and curetting the sinus tracts frequently give relief. Again, the best results have been obtained by excising the fistulous tracts, dilating the urethra and diverting the urinary stream by performing a suprapubic cystostomy. A new urethral tract

was necessary in one case before healing took place. This was performed by doing a retrograde operation for urethral stricture, making a suprapubic and perineal exposure and discarding the strictured area of the urethra.

Urethrocutaneous fistulas either the results of a peri-urethral abscess rupturing through the urethra and to the outside or the direct result of an incision from the outside into an abscess, the incision having been carried into the urethra, produce the same symptoms as the preceding conditions, making it necessary under these circumstances to carry out some surgical procedure. Excising the tract from the outside down to the urethra and suturing the freshened edges of the urethra over a catheter have given a complete closure in two cases. In one case it was necessary to perform this operation, plus diverting the urinary stream by doing a suprapubic cystostomy.

Sterility the direct result of an epididymitis from gonorrhea has occurred on numerous occasions. Seven cases have come to operation in which an epididymo-vasostomy was performed. In only one case was I able to obtain spermatozoa coming through the anastomosis. In this case the patient subsequently became the father of a child.

A plea is here made for more and earlier surgery for the complications of gonorrhea.

CHRONIC PROSTATITIS AND PROSTATIC CALCULUS

TREATMENT BY INCISION WITH THE
ELECTROCAUTERY

GERSHOM J THOMPSON, MD

AND

EDWARD N COOK, MD

ROCHESTER, MINN.

In the last decade the technic of intra-urethral operations for obstruction of the vesical neck has been greatly improved, as evidenced by the contributions of many authors. Numerous instruments have been devised, which not only have simplified this form of surgery but have led to greater knowledge of the pathologic anatomy of the posterior urethra and vesical neck. As a result, various procedures for the correction of disease not strictly obstructive in nature naturally have developed.

In 1931 we were finding various prostatic and posterior urethral lesions which seemed suitable for correction by minor procedures such as electrocoagulation, or incision with the electrocautery. One of us¹ has reported some of these cases. Removal of prostatic calculi by transurethral methods has been recorded by Michel, and incision of large, subacute abscesses of the prostate gland by Multhaupt and Curtis.² Heitz-Boyer³ stated that as early as 1920 he was opening,

by various intra-urethral methods, prostatic and urethral diverticula which he often found in cases of chronic prostatitis of many years' duration. His excellent article was accompanied by a series of urethrograms which gave evidence of relatively large pockets draining into the urethra by narrow ducts. More recently, Davis⁴ has reported a series of cases in which he had noted marked clinical improvement following drainage of such pockets. It is our purpose in this paper further to record our observations at the Mayo Clinic of the past three years, in which time sixty-seven patients have been subjected to operation. All of these patients had single or multiple chronic abscesses and seven had prostatic calculi in association with the infected pockets.

All of these patients had suffered with chronic prostatitis for a prolonged period and had been treated by a variety of methods, including massage, instillation and injection of various antiseptic substances into the prostate gland, urethral and rectal diathermy, subcutaneous and intramuscular administration of vaccine or foreign protein, and, in one case, by suprapubic transvesical drainage. Many of the patients were temporarily improved by such treatment but relief was only transient, after which they often subjected themselves to various other treatments, usually of a different type from that first employed.

The average duration of symptoms before admission was six and two-tenths years and a few patients had been troubled for as long as thirty years. Two patients had multiple perineal sinuses and one a urethroperineal fistula following incision of the prostate gland many years before his admission to the clinic.

The usual symptoms noted by patients with chronic prostatitis were noted by the patients concerned, in addition, it seemed striking that 32 per cent of them complained of definite perineal pain, aching, throbbing or perirectal discomfort. Dysuria of varying degree was a complaint of 41 per cent of the patients. A few gave definite histories of recurrent, acute prostatic abscess, with relief after spontaneous intra-urethral rupture and drainage of purulent material. Of the patients, 15 per cent complained of a chronic urethral discharge, usually in the form of a morning drop, while 6 per cent had suffered with recurrent epididymitis. Metastatic symptoms, such as lumbar pain, sciatic neuritis, and pain in the sacro-iliac or other joints, sometimes with subacute synovitis, were noted by 24 per cent of the patients, and chills and fever not attributable to pyelonephritis or epididymitis had been experienced by 12 per cent. Examination of the expressed secretion revealed prostatitis, grade 4, in fifty-five of the sixty-seven cases and in seven of the remaining twelve the infection was graded 3, in no instance was the prostatitis graded less than 2.

URETHROSCOPIC EXAMINATION

Very careful urethrosopic study is absolutely essential. An instrument with a lens that will magnify the structure is desirable and preferably one that has an angle of incidence of from 45 to 90 degrees. We have not used the variable-incidence lens described by Heitz-Boyer, although no doubt it is the ideal type. As a general rule, one or more dilated prostatic ducts will be found somewhere in the floor of the prostatic

The principle involved is promotion of free drainage through the site of infection, as was described in the first article on this subject. Free drainage is insured by the flow, through the surgically smoothed prostatic urethra, of urine, which flushes the cavity at each voiding. To secure free drainage it was found necessary to excise bits of tissue, as is shown by the dotted lines in figure 2 (left) in thirty cases, the ultimate channel having the appearance of figure 2 (right).

Fig. 2—Left: incision through the posterior vesical lip with a Collings knife; the areas outlined by dotted lines indicate tissue to be excised with a Braasch Bumpus punch of small caliber. Right: appearance of prostatic urethra at completion of operation.

urethra, adjacent to the verumontanum. Ordinary manipulation of the urethroscope usually will cause purulent material to exude from these ducts if purulent material is present, although in an occasional case it is necessary to make direct pressure on the prostate gland with a finger in the rectum or to apply counter pressure on the perineum before pus can be expressed from a deep pocket. The examiner must not be misled by noting thin prostatic fluid which at times will flow from even a normal prostate gland. However there is little likelihood of confusing this fluid with pus, which as it exudes from the duct often resembles paste in consistency.

OPERATION

We believe that nitrous oxide, either alone or combined with ether, provides the best anesthesia. The McCarthy panendoscope has been used almost exclusively in those cases in which electrocoagulation only has been required (twenty-one cases) and the same instrument in combination with the Braasch-Bumpus punch of small caliber when excision of tissue is necessary. The latter instrument is used for excision in preference to a cutting loop, because the electric burn is thus kept at a minimum and ultimate healing is therefore hastened. The depth of the cavity can be ascertained with a rigid electrode, as is shown in figure 1, following which a straight Collings knife is used to incise down to the bottom of the pocket and to make an incision through the posterior vesical lip, if this is necessary (fig. 2, left). This procedure alone was employed in sixteen cases. The straight Collings knife will be found superior to a knife of the curved type, because one can visualize it more easily and hence can avoid a perforation which might result in a major complication from a minor procedure. Calculi (figs. 3, 4 and 5) present in the pockets or embedded in the deep structure of the prostate gland are easily removed by flicking them out into the stream of irrigating fluid and washing them into the bladder, from which they can be aspirated easily by suction if they do not drain out through the cystoscope in the usual manner.

Bleeding points should be stopped by electrocoagulation, but it is best to employ this measure in a minimal degree and, if venous oozing persists, one preferably should rely on drainage by urethral catheter and frequent lavage, to prevent formation of blood clots. There is practically never any postoperative febrile reaction, and drainage by catheter, of more than twenty-four hours' duration for the control of bleeding, seldom has been required.

Postoperative management should consist principally of observation, avoiding prostatic massage for a number of days or, preferably, weeks. The urine may be hazy for a short time and if so it is well to include oral medication in addition to an increased intake of fluid.

IMMEDIATE RESULTS

Following the operative procedures that have been described almost without exception the immediate results were good. The patients who had had definite local symptoms stated that they had experienced marked improvement. In three cases there was some delayed bleeding, in two of these cases bleeding stopped spontaneously, but in the other case hospitalization again, and fulguration of the bleeding point, were required. There were no other postoperative complications.

In a few cases improvement was delayed, and the beneficial effect was not noted until several weeks had elapsed.

REEXAMINATION

We have felt that it is unwise to massage the prostate gland within one month after operation. All patients have been urged to undergo reexamination, either at the Mayo Clinic or at home. Many of them in the absence of symptoms have refused to submit themselves to examination again, but of those cases in which the patients have submitted to such study, in 80 per cent either evidence has been obtained of marked reduction in the amount of infection in the expressed secretion or there has been no evidence of prostatitis. Those patients who returned for reexamination have been subjected to urethroscopy. In no instance has there been evidence of stricture, the site of the excision or fulguration has been well healed, and mucosa has grown down into it in every case.

Fig. 3—Removal of calculi with the Collings knife.

Whether or not symptoms will recur or increase at a later date cannot be stated but fully 90 per cent of patients have been satisfied with their treatment

CONCLUSIONS

1 Chronic prostatitis often persists because of infected pockets or diverticula that drain only through a small prostatic duct

2 Treatment by ordinary methods such as massage, irrigation injection of antiseptic substances, or diathermy results only in temporary relief of symptoms

3 Surgical treatment of these regions by the transurethral route will insure adequate drainage and subsequent improvement in a large percentage of cases

4 The prostatic cavities must be

Fig 4—Prostatic calculi removed in the course of operation. See figure 5

widely excavated in the form of a saucer and if necessary, tissue must be excised to provide free flushing at the time of urination, otherwise infection will persist

5 Calculi embedded in the prostatic tissue which occur either primarily or secondarily to prostatic infection, can be removed by transurethral operation

ABSTRACT OF DISCUSSION

ON PAPERS OF DR. GOLDSTEIN AND DRS THOMPSON AND COOK

DR WILLIAM N TAYLOR Columbus Ohio Drs Thompson and Cook emphasized a type of therapy applicable in many chronically infected prostates. I do not feel that this type of treatment for chronic prostatitis is new but rather that the old punch operations whether performed intra urethrally or suprapubically had veritely in some cases did the same thing as they are advocating with present refined procedures. I have divided prostatitis into two groups (1) chronic prostatitis without morbid structural changes in the posterior urethra or vesical neck (2) those in which there are visible pathologic changes in the way of dilated ducts sinuses crypts and contractures of the neck or stones. The first group should be treated along conservative lines. The second group with the contracted neck is suitable for any type of instrumental treatment so long as it promotes drainage of the bladder and opens widely the infected areas in the prostate. Ten cases of persistent prostatitis, with structural changes, in which I have resorted to instrumental treatment is all that I can add to this discussion. Six of them were treated with the Collings incisor in which the ducts and sinuses were widely exposed at the time the vesical neck was resected. Three have been subjected to similar treatment with the McCarthy resectoscope. I feel that the results have justified the procedures. All these patients have improved symptomatically though they still have cloudy urines, perineal distress and periods of frequency. Three cases in which stones were present in the prostate have shown the greatest improvement. I would emphasize that following resection for this type of prostatitis it is necessary to continue with the older methods of massage and irrigation to obtain a

complete recovery. I am aware of the fact that endoscopic examination of the posterior urethra may not disclose pathologic changes in the infected prostate and I would hesitate to subject such a gland to intra-urethral surgery unless it could be definitely proved that a lesion was present that would respond to drainage. If I advocate instrumental treatment of the chronically infected prostate without structural changes, I feel that much maddlesome and ill advised intervention will result.

DR J SIDNEY RITTER New York It seems no longer excusable to fail to identify definitely by precise instrumental means the prostate seminal vesicle or both as the underlying offending factor and to direct treatment accordingly. Moreover it is now a feasible technical procedure by catheterizing the ejaculatory ducts to locate this focus of infection in the majority of cases. In a smaller percentage of cases in which it is impossible at once to catheterize the ejaculatory ducts, the usual cause for such failure is the edematous congested condition of the verumontanum which may cause partial occlusion or distortion of the duct lumen. However in most of these cases preliminary treatment directed toward the local condition enables one at a later date to accomplish the same result. This whole field of research is tremendously important and well worthy of the investigative efforts of the best minds in the profession.

DR ELMER HESS Erie, Pa Acute gonorrhea and many cases of chronic gonorrhea are seldom referred to the urologist until the occurrence of complications. With Dr Goldstein's experience that the majority of cases of epididymitis clear up with ice support and rest in bed I am in accord. I also believe in epididymotomy when the infection has progressed to the stage of free pus but I condemn epididymectomy on the indications that he gives namely when the lumen of the vas is obliterated when free pus is found and in cases of recurrent epididymitis. Epididymectomy may be useful in certain types of recurrent epididymitis with much fibrosis to relieve the pain. Concerning prostatotomy for acute prostatitis without actual abscess formation again I am obliged to dissent and I am also opposed to any local instillation treatment. The surgical risk with all its dangers added to a condition that is purely medical would make me hesitate a long time before attempting it. I agree with either the perineal approach or the urethral approach in prostatic abscess preferring the urethral one. Suppurative inguinal glands must be opened and drained. I always open a periurethral abscess externally and have had little difficulty in having the process heal. I have never operated on the

Fig 5—Preoperative and postoperative roentgenograms of a patient who had prostatic calculi

seminal vesicles for anything but a tuberculous involvement and have never had a satisfactory result from it. In acute vesiculitis the Belfield male pus tube operation is as contraindicated as it is in acute pus tubes in the female. There are times in gonococcal arthritis when it may be good surgery to do vesiculectomy but I have never done the operation for this indication. Phimosis and paraphimosis call for immediate surgical interven-

tion as the author has pointed out. I should like to add another surgical procedure that has not been mentioned: meatotomy in acute urethritis when drainage is poor because of a small meatus. I would like to ask how Dr Goldstein treats gonorrheal pnelitis. I am in accord with the treatment of cowperitis, urethral stricture and urinary extravasation. The author pleads for more and earlier surgery for the complications of gonorrhea. May I plead for the nontransference of an ordinarily self-limited medical disease to a surgical one?

DR CYRIL K. CHURCH, New York. I cannot agree with Dr Goldstein that increasing pain is an indication for epididymotomy to relieve the edema which I agree with him is the real cause of the pain. The proper treatment for this condition is diathermy, it being necessary of course to have a clamp that fits the testicles accurately and tightly enough. Then by conveying a current through the organ by having electrodes attached on opposite sides one can raise the temperature of the organ to the patient's tolerance. This will convey great heat to the part and consequently promote the circulation through it. Then if one wishes to deplete the tissues of the organ of their excess or edematous fluid all that it is necessary to do is to detach one electrode from the clamp holding the testicle or epididymis and to fix it to a plate on which the patient is lying and so put the current through in that direction, the circulation will be promoted through the spermatic cord and so alleviate the edema and consequently the pain. Epididymectomy should be resorted to only for a recurrent condition. The explanation why prostatectomy does not cure chronic prostatitis is that in most prostatectomies the whole gland is really not removed but only that part of it which causes obstruction to the outflow of the urine. It is that part of the gland which is not removed which continues to harbor infection. Granting that a vesiculectomy should be done at all the technique should be sufficiently good so that the operator can guarantee to the patient that his vas deferens will not be touched or destroyed and he will not be rendered sterile. This operation is highly technical especially in the matter of removing the vesicle without destroying the communication between the vas deferens and the urethra. It would take an extremely skilful operator to be able to give this guaranty to the patient. However, I think that it is possible if one is sufficiently familiar with the field.

DR ALBERT E. GOLDSTEIN, Baltimore. If there is one thing that these meetings do they give an opportunity to hear an honest difference of opinion. Several urologists have stated that we are no better off today than we were thirty or forty years ago that we are still treating gonorrhea in the same way, and still are having the complications that we always had, and still are going through the same routine. The reason we are having so many complications today the reason we are treating the results of complications of gonorrhea by the various methods brought out today is that we have permitted in the early stages in acute prostatitis and prostatic abscess and epididymitis the gonococcus or its effects to get into the mucous membrane of the urethra of the epididymis of the vas and to remain there and act as a focus of infection. In view of the fact that no one else has had anything better to offer, I feel that we might give some of these things a trial by not permitting the gonococcus or its effects to get into the urethra in its early stage. If we went about these things extra-urethrally, I am sure we would get better results. Regarding Dr Hess's statement about not permitting epididymectomy, of course there is a difference of opinion. It seems to me that we both obtain the same results. As to Dr Church's discussion regarding epididymitis we find the lumen obliterated with debris in some cases and in some cases blocked by fibrous tissue. Regarding prostatectomy for prostatitis, I am afraid that he misunderstood the statement. I advised prostaticotomy not prostatectomy.

DR. CHURCH. I stand corrected.

The Measure of Efficiency of Any Protein.—The nutritional efficiency of any particular protein is measured by its yield of amino acids especially of those amino acids which are not synthesized by the organism and which therefore must be included in the food.—Newburgh L. COXA MAGNA

A CONDITION OF THE HIP RELATED TO COXA PLANA

ALBERT B. FERGUSON, MD

AND

M. BECKETT HOWORTH, MD

Director of Roentgenology and Fellow of the New York Orthopaedic Dispensary and Hospital, Respectively
NEW YORK

Coxa magna is a condition of the hip related to coxa plana. To indicate this relationship it is necessary to outline the etiology of coxa plana, which is more fully discussed in a recent article on coxa plana.¹

The common type of coxa plana is a nutritional disturbance of the upper femoral epiphysis due to a certain degree of interference with its circulation by sclerotic changes about the femoral neck. The sclerosis is the result of a preceding inflammation at the joint. When there is a circulatory disturbance of this kind not sufficiently severe to produce coxa plana, there may be enlargement of the femoral head and neck without other noteworthy changes. These cases present the clinical features of coxa plana but are characterized roentgenographically by enlargement of the femoral head and neck instead of by flattening and irregular ossification of the head. This condition is designated coxa magna.

Fig. 1—Typical coxa magna. The femoral head and neck are broad. Bony changes suggestive of coxa plana were not present at any time.

We are presenting thirteen cases of simple coxa magna and twelve cases illustrating the relation of coxa magna to other conditions.

CLINICAL FEATURES

Of the thirteen children with simple coxa magna, six were boys and seven girls. The right hip was affected in six instances, the left in seven. No bilateral cases were recognized. None of the children were abnormal in stature and none were definitely overweight. Every child gave definite or suggestive evidence of a possible source of infection. The tonsils were diseased in five and had been incompletely removed in two and removed in five others. At or shortly before the onset of hip symptoms, two patients had bronchitis, one chickenpox, one croup, one cardiac disease and

Read before the Section on Orthopaedic Surgery at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.
1. Ferguson, A. B. and Howorth, M. B. *J. Bone & Joint Surg.* 16: 781 (Oct.) 1934.

purulent pimples on the legs, one jaundice with fever, and one in unexplained leukocytosis (19,600)

The onset of hip symptoms was gradual in five instances in which there was no history of injury and in one patient who had had occasional falls on the hip. The onset was sudden in four cases without trauma and in three children who had had an injury to the hip, two of the injuries being trivial. Hence trauma

Fig 2—Congestion and sclerosis of soft tissues about the femoral neck in coxa magna

did not appear to be the cause of the condition but it might have aggravated or directed attention to the symptoms

The first symptoms noted were pain in all cases, with a limp also in four. The pain was referred to the knee in two instances, to the thigh in one, and to the hip in ten, with radiation to the thigh or knee in three of these. The age at the onset of symptoms varied from 2 to 14 years, the mean being 10 for both the boys and the girls. The patients were first seen from three days to one year after the onset of symptoms, except in one case, which was seen after two years. Six children had had symptoms for one year.

The physical signs in these cases resembled those of coxa plana. Limitation of motion varied from little to extreme, each motion being subject to limitation. Eight patients had flexion deformity. Acute signs, such as tenderness, spasm and pain on motion, were present in all but one of the cases. Atrophy of the thigh was present in ten instances shortening in six varying from one-eighth to one-half inch, and in one case the affected leg was seven-eighths inch longer than the normal leg.

ROENTGEN FEATURES

At the first roentgenographic examination in each case there was broadening of the femoral head and neck, varying from one-sixteenth to five-sixteenths inch

(fig 1). The cartilaginous joint space was wide in four instances, normal in seven, and thin in two. The capsule of the joint appeared distended in six hips and not distended in seven. The broadening of the head and neck tended to increase for a varying time, while the other changes tended to revert to normal.

PATHOLOGY

An exploration was done in seven of the thirteen hips. The outstanding feature in each hip was thickening of the tissues about the femoral neck, the synovial membrane and the capsule. These soft tissues were congested in most of the hips (fig 2), usually with some pannus formation, while in the others the tissues were sclerotic. Small areas of mononuclear infiltration were often present (fig 3) and the vessels were usually thick walled. The bone and cartilage were essentially normal, although in some instances the cartilage was slightly pitted and the bone quite vascular. These changes were the same as we have found in early coxa plana and in the preslipping stage of slipping epiphysis. They definitely presented the picture of changes in the soft tissues about the femoral neck disturbing the circulation of the femoral head, with no primary lesion of the bone or cartilage.

Cultures of tissues from the hip yielded no growth in the four instances in which they were taken, and there was nothing in the postoperative course to suggest that an area of active infection had been entered. The Wassermann test was negative in the nine cases in which it was done. The tuberculin test was positive in five of nine patients. There was leukocytosis in two of the seven cases in which the blood was examined.

DIAGNOSIS

The diagnosis of coxa magna is made when a hip presents clinical features of a mild, acute or subacute arthritis similar to those of coxa plana or the preslipping

Fig 3—Mononuclear infiltration and sclerosis in the soft tissues about the femoral neck in coxa magna

ping stage of slipping epiphysis but roentgenographically presents enlargement of the femoral head and neck without the changes characteristic of the other conditions mentioned. The condition most difficult to differentiate is early tuberculosis with slight overdevelopment of the femoral head. In this condition, local decalcification is apt to be a prominent feature. In questionable cases the patient should be allowed to rest in bed without immobilization. In these circumstances

the symptoms and physical signs will improve rapidly in coxa magna, and slowly or not at all in tuberculosis. If the diagnosis remains doubtful, exploration of the hip is to be recommended.

COURSE AND TREATMENT

The symptoms and physical signs in coxa magna ended to improve with rest or to run a long course

Fig. 4 (case 14)—Beginning coxa magna nine months after drainage of the hip for acute suppurative arthritis. The hip is clinically normal.

with eventual improvement if untreated. Persistent limitation of motion usually occurred after immobilization by traction, brace or plaster spica or after traumatism by a forceful stretching or other manipulation. Exploration had no unfavorable influence on the course.

In the thirteen cases under consideration, four had no treatment and their results are unknown. One hip was treated by rest in bed for one month, during which time a purulent tonsillitis which was present at the onset of hip symptoms, was also treated. At the end of this time there was excellent motion at the hip with-

Fig. 5 (case 14)—Coxa magna with marked elongation of the femoral neck five years after drainage of the hip for acute suppurative arthritis. The hip is symptomless.

out symptoms. Of the hips that were explored, three were improved when the patients were allowed to be up and, at the end of one year, were symptomless except for occasional pain, and in two years were symptomless with excellent motion. Another child was kept in bed one month and had a tonsillectomy during that time. She was improved but symptoms recurred one month

later, whereupon a brace was applied for four weeks without improvement. The hip was then explored. There was excellent motion with no symptoms when she was allowed up five weeks after the operation. She has continued symptomless. Two patients wore a plaster spica for five months. They had considerable limitation of motion persisting two years thereafter, although they had no pain. One of these hips was explored one year after the application of the spica, the stiffness persisted and there was occasional pain during the next six years. In another case the hip was explored and traction was applied for two weeks, after which the patient was allowed up, improved. Symptoms became worse in three months and marked limitation of motion continued. The hip was stretched one year later. Thereafter motion was very limited and an arthroplasty was done one month later, but no motion was gained and pain was still present two years later. The thirteenth patient wore a brace for two years with no improvement. The hip was then explored and one month later the hip was fused, on suspicion that the condition was tuberculous, although this was not proved.

Fig. 6 (case 17)—Marked coxa magna. The articular cartilage is thin and the surface of the head is irregular in density. These changes suggest continued or intermittent infection in the joint during the development of coxa magna. This patient had intermittent attacks of otitis media throughout the duration of hip symptoms.

From the foregoing it is evident that, in general, the more vigorous the treatment the poorer the result. These cases suggest that the proper treatment for coxa magna is rest in bed without immobilization, treatment of focal infections, and exploration of the hip when it is necessary to distinguish tuberculosis.

DEVELOPMENT OF COXA MAGNA

In each of the thirteen cases here reported as simple coxa magna the cause of coxa magna appeared to be a disturbance of circulation of the femoral head produced by sclerotic changes in the soft tissues about the femoral neck following subacute arthritis, probably infectious. The disturbance of circulation of the femoral head producing coxa magna can be developed from causes other than subacute arthritis. The following cases illustrate various origins and effects of such disturbance of circulation.

CASE 14—A boy aged 3 years, had acute suppurative arthritis at the hip which was drained on the seventeenth day. The result was a normal hip, except that the soft tissues were sufficiently scarred to result in disturbance of circulation of the femoral head. In nine months the femoral head was three sixteenths inch broader than the normal and the neck was elongated (fig. 4). This deformity has continued during the five

years to the present time, although there was no pain and no limitation of motion (fig 5)

CASE 15—A girl in her infancy had an acute inflammation at the hip with marked effusion resulting in dislocation. When the effusion had subsided, the dislocation had become reduced. No operation was performed. Three years later the femoral head was one fourth inch broader than the normal. In this instance a definite acute arthritis resulted in sufficient sclerotic changes about the femoral neck to interfere with the circulation of the femoral head.

CASE 16—A boy, aged 15 years, had a polyarthritis which was diagnosed as rheumatoid arthritis. The hips, knees and elbows were involved. At the age of 17 the polyarthritis had subsided but the right femoral head was five-sixteenths inch broader than the left which appeared to be of normal width. At 23 the condition was the same, with limitation of motion at the right hip but no symptoms.

When an infectious arthritis continues chronically development is usually impaired. Occasionally, however, a coxa magna suggests that low grade infection is still active after enlargement is well developed, as in case 17.

CASE 17—Seven years after the onset of pain and limitation of motion at the left hip the femoral head in a girl, aged 14 years, was three eighths inch broader than the normal, but continued activity of low grade infection was suggested by thin-

Fig 7 (case 23)—Marked elongation of each femoral neck in bilateral slipping epiphysis without definite displacement.

ning of the joint space, local decalcification and marked irregularity of density of the surface of the femoral head (fig 6). The patient had chronic otitis media with intermittent discharge from the ear during the period of the hip disease. She wore a long leg brace most of this time.

Thickening or sclerosis of soft tissues about the femoral neck may result from the inflammatory reaction produced by an adjacent lesion.

CASE 18—A patient had a tuberculous abscess of the ilium near the hip at the age of 9 years. At operation the abscess was curetted and filled with bone chips. Through a separate incision the joint was opened. The soft tissues at the joint were thickened and sclerosed but no evidence of infection was found, nor has clinical evidence of infection of the joint appeared in the three years since the operation. The femoral head was five sixteenths inch broader than normal before operation and also three years later.

CASE 19—A boy, aged 6 years, had an acute abscess in the left gluteal region. This was drained. No communication with bone or joint was found. The lesion healed with slight limitation of motion at the hip, which has continued for ten years. At the time of operation the left femoral head was three sixteenths inch broader than the right and two years later it was nine sixteenths inch broader.

In the reduction of congenital dislocation of the hip, tension of the soft tissues about the femoral neck may result in disturbance of circulation of the head. The

usual sequel to this is coxa plana but occasionally there is merely an enlargement of the femoral head and neck—a coxa magna.

CASE 20—A patient had bilateral congenital dislocation of the hips. Both were reduced at the age of 2 years. The right hip did not stay in. It was again reduced and, within the year, an osteotomy of the femur was done to correct anteversion. Reduction was permanent but at the age of 6 the

Fig 8—Bilateral coxa magna following coxa plana. In the hip on the left the deformity indicates that the condition was complicated by avulsion at the ligamentum teres with reunion of the displaced fragment. Bilateral coxa magna is seldom recognizable because the deformity in the less affected hip may not appear definite in the absence of a normal for comparison.

right femoral head was unusually broad, three-sixteenths inch broader than the left and continued so until the child was 8. The result of the reduction was excellent.

In coxa plana the circulatory disturbance that produces coxa magna is present and broadening of the head is often a prominent feature, especially in advanced cases.

CASE 21—Coxa plana began to develop in a boy, aged 7 years. At the age of 8 a plaster spica was applied for three months followed by a brace for two years. At the age of 12 the coxa plana had reached the residual stage and the femoral head was one-half inch broader than the normal.

Broadening of the femoral head may likewise be a feature of slipping epiphysis, as in the following instance.

CASE 22—In a girl pain in the hip began at the age of 10 years. Roentgen examination demonstrated the presence of the preslipping stage of slipping epiphysis. After two months in bed the hip was clinically normal, but there was slight broadening of the femoral head. Six months later slight displacement of the head occurred and a plaster spica was applied for three months. At the age of 12 the femoral head was one-half inch broader than the normal.

Fig 9 (case 25)—Marked coxa magna with massive arthritic osteophytic production at the age of 17. Hip symptoms began at the age of 2. The hip was explored at 10.

When the preslipping stage of slipping epiphysis subsides with little or no displacement occurring, over-

development may take the form of elongation of the neck

CASE 23—The patient had a limp during the adolescent rapid growth period, and the hips became prominent. When seen at the age of 20 each femoral neck appeared about 1 inch longer and somewhat broader than normal (fig 7)

In coxa plana, the bone adjacent to the ligamentum teres may remain well nourished by vessels in that ligament. In such a case the healthy bone near the ligament may appear in the roentgenogram to have separated from the remainder of the head. When the fragment later reunites with the broadened head, the result is a very broad head with a bulbous projection medially at the site of the ligamentum teres. Case 24 is an example of this.

CASE 24—A boy, aged 7 years, had a limp and pain in both hips. This was untreated and did not continue many weeks. When seen at the age of 28, each femoral head was fully 1 inch broader than normal and the right head had a deformity indicative of previous avulsion at the teres ligament.

Degenerative arthritis may be a sequel of coxa magna, as in all conditions related to coxa plana. Case 25 (fig 9) illustrates the presence of marked osteophytic formation in marked coxa magna at the age of 17 years.

CONCLUSION

Coxa magna is a condition characterized by enlargement of the femoral head and neck due to local disturbance of circulation in a child clinically presenting the symptoms and signs of coxa plana without the abnormalities of bone or cartilage characteristic of coxa plana or slipping epiphysis.

The importance of coxa magna is twofold. First, if the condition is not recognized, unnecessary or harmful treatment may be used. Second, it is an essential feature in completing a conception of the conditions related to coxa plana.

The treatment of coxa magna should be rest in bed without immobilization and removal of foci of infection.

Coxa magna may arise in a variety of ways, which are illustrated here by selected cases.

420 East Fifty-Ninth Street

ABSTRACT OF DISCUSSION

DR OSCAR L. MILLER, Charlotte, N. C. In 1930 I read a paper before this section on acute transient epiphysitis of the hip joint. I had followed a series of cases of this disease for several years. I described transient epiphysitis in that paper as a disease of childhood, the cases reported showing an average age of $7\frac{1}{2}$ years. The children affected were usually active and vigorous and no prodromal period of indisposition or declining health was observed. Local symptoms about the hip varied from negligible complaint to marked muscle spasm, deformity and temporary prostration. Moderate elevation of temperature and leukocytosis were the rule. Early remission of symptoms followed tonsillectomy in about 80 per cent of the cases. Some cases appeared to be associated with the acute exanthems. Roentgenograms in transient epiphysitis of the hip may appear negative for a while in the invasion period, but eventually some disturbance of bone texture should be observed along the proximal or distal border of the epiphysal line and evidence of exudate into the joint with distention of the capsule. My conception of the pathology of transient epiphysitis is that small showers of infected emboli lodge as infarcts near the epiphysal line within the hip joint and the extent of disease resulting depends on the virulence of the organism infecting and the resistance of the subject. I believe that the majority of hip lesions in childhood have their origin in the more or less

terminal vessels about the femoral epiphysis and that the soft parts are secondarily involved from infected exudate. The treatment in all the cases of transient epiphysitis of the hip joint was rest in bed for a period, traction on the leg when muscle spasm was present, and clearing up any known foci of infection. All of the patients made complete recovery. That is my conception of one type of hip disturbance that might result in coxa magna. Just whether this overgrowth occurs from an increase or a decrease in the blood supply, I do not know. I had thought it occurred from an increased blood supply. I wish to petition that, before accepting coxa magna as a special entity, the authors acknowledge, as a definite disease its parent or forerunner, acute transient epiphysitis of the hip.

DR M. BECKETT HOWORTH, New York. In two articles accepted for publication in the October issue of *Bone and Joint Surgery* Dr. Ferguson and I have reported eighty cases of coxa plana and in one of the articles we have described five different types of ischemia into which we think these conditions can be grouped. The cases we here report which we have been able to follow through are cases that belong in the first class of ischemia—simple, uncomplicated. When coxa plana or anything else is present we do not call the condition coxa magna. The cases which Dr. Miller showed we would classify as due to group 2 ischemia associated with a definite lesion of the femoral neck, and they would not come in the former classification.

COMPARISON OF THE URINARY TRACT IN PREGNANCY AND PELVIC TUMORS

EDGAR C. BAKER, MD

AND

JOHN S. LEWIS JR., MD

YOUNGSTOWN, OHIO

The advent of intravenous kidney dyes has opened up additional fields of investigation. Prior to the period of the dyes, the investigation of the urinary tract in pregnancy was disturbing and possibly harmful to the patient. In consequence, comparatively few complete studies of the normal urinary tract in pregnancy were done. In the last few years, several such studies have been made.¹ These studies have disclosed certain facts which have been valuable in clinical investigation of pathologic conditions existing in pregnancy, such as pyelitis.

The study by intravenous dyes of the urinary tract in pregnancy meets ideal conditions. It is known that intravenous urography succeeds best when a certain degree of obstruction between the kidney and the bladder coexists with a fair to good excretory function of the kidneys. Such a combination of clinical circumstances is found in pregnancy. These studies have revealed a high degree of dilatation of the upper urinary tract. This dilatation is more marked on the right side.²

In several such series reported,³ the right side was dilated in from 90 to 100 per cent. The left side

showed varying figures but never approached the high figure of the right side

In our own series the right sided dilatation was 92 per cent (table 1) The left side showed dilatation in 52 per cent These figures compare favorably with the statistics given in other series

It was early apparent that the position of the fetus had no effect on the dilatation The occurrence of dilatation was found in breech presentations, in right and left occipital presentations, and in twin pregnancy with both twins lying transversely In one case the fetus changed from an occiput to a breech presentation Examination was done in both positions Right sided dilatation was found in both positions

TABLE 1—Percentage of Dilatation

	Pregnancies	Tumors
Both sides	52	63
Right side	40	37
Left side	0	0
Neither side	8	0

In our series no real dilatation occurred until the uterus rose into the abdomen The dilatation was more pronounced after the fourth month until close to term, when it appeared to subside slightly in some cases At the third month, however, the upper tract on the right side showed better filling with the excreted dye than is usually seen in normal, nonpregnant patients

Fig 1—Pregnancy showing good filling of upper urinary tracts No real dilatation

The stasis thus demonstrated helps to explain the reason for the frequency of pyelitis or urinary infection in pregnancy

Several explanations have been advanced for the dilatation, and especially for the right sided preponderance Chief among the causes listed in the current literature are (1) mechanical factor,⁴ (2) hormonal

factor,¹⁰ (3) increase in bile salts¹⁶ attended with hypertrophy of the lower ureters, and (4) congestion of the lower ureters associated with increased blood supply to the pelvic organs It is our belief that the mechanical factor is of prime importance This factor was called to our attention by a postmortem examination of a case a few days post partum In studying the relations of the organs after the intestine was dis-

Fig 2—Ovarian cyst the size of a seven months pregnancy Upper urinary tracts well filled

placed, it was readily apparent how firmly the post-partum uterus fit against the right pelvic brim On the left side the sigmoid⁵ formed a soft cushion between the uterus and the pelvic brim The left ureter passed behind the sigmoid over the pelvic brim The sigmoid formed a soft, yielding and changing cushion between the uterus and the left ureter

Following this lead a few patients were given intravenous dye At the time when the urinary dilatation was well visualized, a weak suspension of barium sulphate was given by rectum to outline the lower colon Roentgenograms taken in the oblique positions showed clearly the relation of the sigmoid to the lower left ureter We feel that the torsion of the uterus to the right—a fact found in any standard textbook of obstetrics—is due to the sigmoid We have failed to find this fact given any emphasis, usually it is not even mentioned It seems a logical explanation of the cause of the rather marked right-sided preponderance of urinary dilatation This is especially true if the mechanical theory is to hold any weight

Chemically there are two other conditions that simulate pregnancy in their effect on the urinary tract These conditions are dissimilar in origin and cannot have the same hormonal or metabolic effect on the patient as that found in pregnancy The two conditions that cause this effect on the upper urinary tract are (1) the fibroma of the uterus of large size and rather uniform outline

⁴ Opitz: *Ztschr f Geburtsh u Gynak* 4: 209 1905

⁵ Carson W J: *Ureteral Dilatation of Pregnancy Autopsy Findings* *J Urol* 16: 167 (Sept) 1926

and (2) the large ovarian cyst. It is of course difficult to find a large series of such cases to study. By cooperation of the surgical staffs we have investigated all such cases that we could obtain. The results of this investigation have more strongly confirmed our belief in the mechanical cause of the urinary stasis in pregnancy.

Fig. 3—Pregnancy near term. Marked right sided dilatation.

Our series of fibromas and ovarian cysts number twenty-three. Of this number, seven cases are not included because of their small size. In these cases the tumor was less than the size of a three months pregnancy. In these seven cases of small tumors the upper urinary tracts were well visualized but showed no real dilatation. This condition was similar to that found in pregnancies of comparable size.

TABLE 2—Distribution of Dilatation in Eight Fibromas and Eight Cysts

	0	+	++	+++	++++
Right pelvis	0	0	32	44	12
Left pelvis	38	38	24	0	0
Right calices	6	19	31	31	13
Left calices	38	56	0	0	0
Right ureter	0	10	31	44	6
Left ureter	63	10	10	0	0

The other sixteen cases were of a size comparable to that of the pregnant uterus in which we found real dilatation. These sixteen cases (table 1) all showed dilatation of the right upper urinary tract at some point. Eight of these cases were fibromas and eight were ovarian cysts. All fibromas that had small localized fibromas pressing directly on the ureter were not included. All cases have been proved by operation.

Fifteen cases showed dilatation of the right pelvis (table 2). Ten cases showed dilatation of the left pelvis. Fifteen cases showed dilatation of the right calices. Ten cases showed dilatation of the left calices. Sixteen cases showed dilatation of the right upper ureter. Six cases showed dilatation of the left upper ureter.

In all cases in which the left side was dilated, the right side showed greater dilatation. Three of the ovarian cysts originated from the left ovary.

Some of these cases show the same lateral deviation (table 3) of the lumbar ureter that is seen frequently in pregnancy. Six cases of the twenty-three showed

TABLE 3—Deviation of Ureter

	Lateral Displacement of Lumbar Ureter in Tumors per Cent	Elongation with Looping of Ureter per Cent

TABLE 4—Visualization of the Pelvic Ureters

	Pregnancies per Cent	Tumors per Cent
Neither side	46	53
Left side	34	17
Both sides	12	30
Right side	8	0

lateral deviation of both ureters. Three cases showed this on the right side only and two cases on the left side only.

One case showed elongation with a bilateral looping of the ureter, and six cases showed a similar condition on the right side.

Fig. 4—Large left ovarian cyst. Marked dilatation of the right upper urinary tract.

As in pregnancies, the visualization of the pelvic ureter was not constant. The cases in which it was seen (table 4), while not statistically exactly alike, were comparable in appearance in the pregnancies and the tumors.

Grading of the degree of involvement (table 5) in both conditions was comparable. The greatest percentage was found in the +++ grading on the right side.

Contrary to other data in the literature, we found that dilatation in the tumor series could become as extreme as in pregnancy.

One case is particularly illustrative (fig 4). In a girl aged 15 years, the abdomen was distended with an ovarian cyst extending to the xiphoid process. At operation the cyst was found to originate in the left

ovary, yet the intravenous urinary examination disclosed a marked right sided dilatation. Several other cases were of nulliparous women. No possibility of a previous pregnancy causing the dilatation was admissible. In a few cases of tumors investigated postopera-

tionally, the dilatation of the urinary tract disappeared following the removal of the tumor. This coincides with the return to the apparent normal condition of the postpartum urinary tract.

There is roentgenologic evidence that appears to support the mechanical obstructive theory. In some cases of stone obstruction of the ureter, or other mechanical obstruction, the following phenomena are frequently observed when intravenous dye is administered. On the normal side the pelvis, calices and ureter are visualized almost immediately. On the obstructed side a faint filling of the calices first appears. As the excretion of dye continues, the calices become more dense. Then the dye diffuses into the pelvis and

finally and very slowly into the ureter. In any case of pregnancy or tumor in which there is any real stasis, the same phenomenon is seen. In the series of cases that is presented this observation was infrequent on the left side and was fairly frequent on the right side. The unilateral evidence of stasis points to some other causation than that of hormones which should act bilaterally.

One other clinical fact points strongly to the mechanical obstructive theory. Pregnant women seriously ill with infection of the upper tract who have been treated by one of us (J. S. L. Jr.) without instrumental intervention have responded to the prolonged knee-chest position. This position removes the mechanical obstructive factor by allowing the weight of the pregnant uterus to come against the anterior abdominal wall. The pressure against the pelvic brim is relieved.

SUMMARY

The common factor in dilatation of the upper urinary tract in such diverse conditions as pregnancy and large pelvic tumors of pelvic origin is a mechanical one. Hormonic and metabolic factors can hardly be the same. The condition is more marked on the right side. In addition, postural drainage gives relief in clinical cases of infection of the upper tract.

CONCLUSIONS

1. There is a high degree of dilatation of the upper urinary tract in pregnancy, in large ovarian cysts and in fibromas of the uterus.

Fig 5—Pregnancy near term. Both upper urinary tracts dilated, right side more marked.

ovary, yet the intravenous urinary examination disclosed a marked right sided dilatation. Several other cases were of nulliparous women. No possibility of a previous pregnancy causing the dilatation was admissible. In a few cases of tumors investigated postopera-

tively, the dilatation of the urinary tract disappeared following the removal of the tumor. This coincides with the return to the apparent normal condition of the postpartum urinary tract.

There is roentgenologic evidence that appears to support the mechanical obstructive theory. In some cases of stone obstruction of the ureter, or other mechanical obstruction, the following phenomena are frequently observed when intravenous dye is administered. On the normal side the pelvis, calices and ureter are visualized almost immediately. On the obstructed side a faint filling of the calices first appears. As the excretion of dye continues, the calices become more dense. Then the dye diffuses into the pelvis and

Fig 6—Large fibroma of uterus. Both upper tracts dilated, right more than left.

2. The dilatation of the right tract is greater and more common.

3. The cause is largely mechanical pressure.

4. The sigmoid plays an important part in protecting the left ureter and probably is the cause of the torsion of the uterus, with resultant increased pressure on the right ureter.

ANTIRACHITIC COW'S MILK

COMPARATIVE STUDY OF ANTIRACHITIC VALUE OF
IRRADIATED COW'S MILK AND OF MILK
PRODUCED BY COWS FED IRRADIATED YEAST

HENRY J GERSTENBERGER, M.D.

ARTHUR J HORESH, M.D.

A L VAN HORN, M.D.

CLEVELAND

W E KRAUSS, PH.D.

AND

R M BETHKE, PH.D.

WOOSTER, OHIO

The following report presents the results of a study made at the Babies and Childrens Hospital of Cleveland to determine the comparative antirachitic efficacy for human infants of two milks produced and assayed at the Ohio Agricultural Experiment Station Wooster,

and kept under the same environmental conditions and that the milks have the same rat unit potency. The desired potency was set at approximately 55 Steenbock rat units per quart.

PRODUCTION

Six disease-free Holstein cows were selected from the Ohio Agricultural Experiment Station herd. These were divided into two groups of three each in such a manner that the groups were as nearly alike as possible with respect to milk production, fat percentage and stage of lactation. All the cows received the same basal ration, consisting of excellent quality alfalfa hay and a grain mixture made up of yellow corn meal, ground oats, wheat bran, and linseed oil meal. The cows were kept under winter feeding conditions throughout the study, a small amount of exercise being obtained each suitable day by turning the cows out into a vegetation free lot.

One group of cows received in addition to the basal ration an amount of irradiated yeast shown by preliminary trial to be necessary if the cows were to pro-

Ohio. The one milk, labeled L milk, was made antirachitic by irradiation, the other, labeled Y milk, by feeding the cows irradiated yeast.

PART I PRODUCTION AND ASSAY¹

By W E KRAUSS, PH.D., AND R. M. BETHKE, PH.D.

One premise on which a satisfactory comparison of different vitamin D milks must be based is a supply of such milks carefully controlled with respect to production and potency. Realizing this, arrangements were made to produce and to control at the Ohio Agricultural Experiment Station two types of vitamin D milk and to furnish these milks to the Babies and Childrens Hospital of Cleveland. One of these milks was produced by feeding cows irradiated yeast, the other by subjecting milk to the rays of a carbon arc lamp. It was intended that the two milks originate from cows fed alike, except for the yeast supplement,

Averages	1.0	3.92

* May 31 to Sept 13 1934

The apparatus used in the irradiation process consisted of a carbon arc lamp² the light from which was reflected onto a thin film of milk flowing over a small surface cooler at the rate of 960 cc per minute. The lamp, equipped with Industrial C carbons at 20 inches from the milk film, was operated at 60 amperes. The milk that was irradiated came from the group of cows not receiving the yeast supplement.

The milks prepared as described were cooled, bottled, iced and shipped to the Babies and Childrens Hospital

The following key letters were used in marking each bottle, and these letters have been retained in referring to the milks throughout this paper. Y, milk from cows fed irradiated yeast, L, irradiated milk, S, skimmed milk.

CONTROL

In order adequately to control the potency of the milk being shipped it was felt desirable to attempt to have samples of this milk under continuous assay. A small amount of Y milk and of L milk was taken out of each

Fig 2—Line tests of rats fed as follows: A 75 mg of Y milk fat (same sample as in fig 1) B 75 mg of L milk fat (corresponding sample) (See table 6). The line tests of the rats fed 50 mg and 75 mg of Y or L milk fat from the composite samples representing the period January 30 to April 14 1934 showed that the same relationship existed between the fats from the two sources as shown in figures 1 and 2 (See table 5).

of Cleveland four times a week in the quantity specified. In addition there was included in each shipment a specified amount of skimmed milk obtained by sepa-

assay. Owing to the fact that 'rickets resistance' was encountered during the early period of assaying the data from less than eight animals were used in arriving at a potency evaluation in a few cases. The results of these assays are given in table 1.

Fig. 3—Blood serum calcium, inorganic phosphate and phosphatase curves and degree of healing as revealed by roentgenogram in a case of so-called spontaneous healing rickets (J. B. see also Figs. 4, 5, 6 and 7). This case is given as an example of the kind that is eliminated by the preliminary treatment free observation period used by the authors and one that if not excluded would have led to erroneous results. In this chart and subsequent charts the columns consisting of four lines represent mild rickets; of three lines moderate rickets; and of two lines marked rickets. The black areas in the columns indicate the presence and extent of healing. The vertical dotted line indicates the end of the four week observation period and the beginning of treatment.

* See footnote to table 3

comparable in vitamin D content from period to period and that there was no measurable difference between the average potencies over the entire period. Owing to the fact that in the first several assays considerable difficulty was experienced in developing the proper

degree of rickets, it seemed to us that further checks on the relative potencies needed to be made, particularly since the milks were fed at only one level. If the assays made after April 1 are considered by themselves the results may be interpreted as indicating a larger content of vitamin D in the L milk. The last eight assays reported in table 1 and all those reported in table 2 were not complicated by "rickets resistance."

Fig. 4—Lateral photographic view showing chest deformity in patient J. B. 14 months of age.

These line-test readings were checked several months later by reading the opposite bones, which had been preserved in 4 per cent solution of formaldehyde U. S. P. The average values of these second readings were almost identical with the first. After May 30, 1934, when the last feeding of L milk to infants was made, the average potency of the Y milk during the remainder of the period when this milk was fed was exactly at the desired point (table 2).

As a further check on potency it was felt desirable to compare composite samples of fat obtained from small samples of milk taken from each kind of milk when shipped. It was assumed that vitamin D was practically entirely associated with the fat and that a prophylactic trial on composite samples of fat representing the entire period during which both milks were fed would yield more definite data in terms of bone ash values than could be obtained when arbitrary line-test values were used as criteria. Conse-

quently two composite samples of the fat from each kind of milk were made: the first representing the period from Jan. 30 to April 14, 1934, and the second the period from April 16 to June 2, 1934.

Weanling rats were fed in addition to the standard rickets-producing diet (No. 2965), 40 mg or 60 mg daily of Y or L butter fat for four weeks. At the end of that time the animals were killed, their radii and

ulnas examined for calcification and the amount of ash in the moisture-free fat-free femurs determined. The results obtained are shown in tables 3 and 4.

In both trials significantly greater bone ash values were obtained with 40 mg and 60 mg, respectively of L fat than with 40 mg and 60 mg respectively of Y fat, and in each case the bone ash values obtained on 40 mg of L fat or 60 mg of Y fat were not significantly different. If the standard prophylactic procedure as followed here is to be considered a measure of vitamin D potency these results indicate that fat from the L milk fed to the infants contained more vitamin D than did that from the Y milk and that the relationship between their potencies was in the ratio of 3:2. The differences obtained could not have been due to a greater concentration of vitamin D in the fat of the L milk because the two milks had the same fat content (table 1).

and 240 mg of dried Y milk, the ratio again being 3:2. A similar ratio was found to exist in the curative assay (table 7).

It would seem to be evident, therefore, that the curative assays made on the liquid milks as fed (table 1) did not give a true evaluation of the actual or relative vitamin D potencies of the two milks. This may be attributed to a failure of our animals to develop the proper degree of rickets during the earlier assays (up to April 1) and to the fact that the milks were fed at only one level.

Fig 6—Left wrist of patient J B. The one at the left was taken on the day of admission. Moderate rickets is present with signs of healing. The one at the right was taken one week after admission and shows further healing. Blood serum calcium was 9.4 inorganic phosphate 3.5 phosphatase

Fig 7—Left wrist of patient J B. Right taken three weeks after admission. Serum calcium 10.4 inorganic phosphate 5.3 phosphatase 0.5. Both roentgenograms show a marked increase in healing although no specific therapy had been administered since admission. The healing therefore was due to the influence of the antirachitic factor somehow administered before admission to the hospital (so-called spontaneous healing).

and the dried L milk thus obtained were then assayed curatively and prophylactically with rats. The results of the curative trial are given in table 7 and those of the prophylactic trial in table 8. As in the case of the butter fats (tables 3 and 4), the bone ash values of the rats receiving 160 and 240 mg of dried L milk are significantly greater than those of the rats receiving 160

The next step consisted in assaying the composite fat samples curatively. From the data thus obtained (tables 5 and 6 and figs 1 and 2) it again becomes apparent as in the prophylactic trials, that the L fat contained more vitamin D than did the Y fat and that the ratio was on the order of 3:2.

As a further step in attempting to reconcile the results obtained on the liquid milks and the fats milk from the two sources of supply over a three weeks period and dried.

The dried Y milk of the curative trial was then assayed with rats. The results of the curative trial are given in table 7 and those of the prophylactic trial in table 8. As in the case of the butter fats (tables 3 and 4), the bone ash values of the rats receiving 160 and 240 mg of dried L milk are significantly greater than those of the rats receiving 160

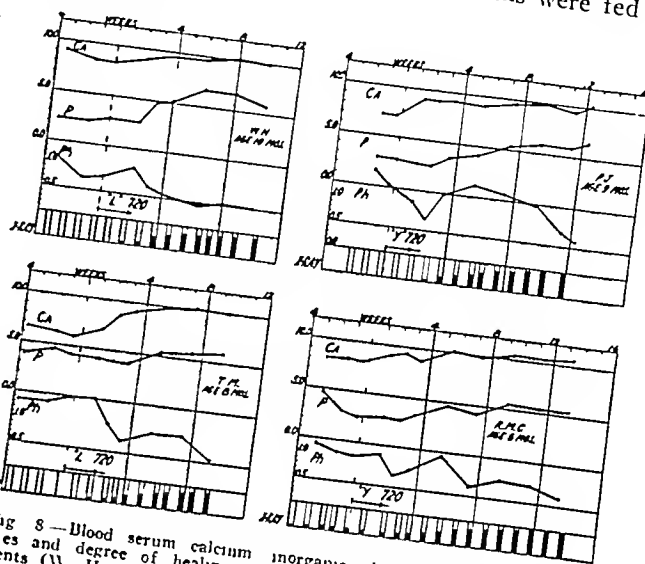

Fig 8—Blood serum calcium curves and degree of healing as revealed by roentgenogram for two patients (J, H and T, V) receiving 720 cc of L milk and for two patients (C, A and R, M, C) receiving 720 cc of Y milk. All four patients had marked rickets.

Fig 9—Blood serum calcium curves and degree of healing as revealed by roentgenogram for two patients (J, C and R, T) receiving 720 cc of L milk and for one patient (C, A) receiving 720 cc of Y milk. Of these three patients J, C had mild rickets and the other two moderate rickets.

CONCLUSION

Considering primarily the curative and prophylactic assays of the composite butter fats and of the dried milks, it must be concluded that of the milks used in this study the irradiated milk contained per unit of measure, more vitamin D than did the yeast milk. More specifically, the irradiated milk contained approximately 80 and the yeast milk approximately 55 Steenbock rat units per quart.

3 In this paper two means are considered to be significantly different when their actual difference is three or more times the square root of the sum of the squares of their probable errors. This means that the odds are 22 or more to 1 that the difference is not due to chance.

PART II CLINICAL EVALUATION⁴

BY HENRY J GERSTENBERGER MD, ARTHUR J HOESH MD, AND A L VAN HORN, MD

The question whether a chosen dose of a supposedly antirachitic agent can or cannot completely heal a given case of human rickets and at what speed can be

Fig 10—Left wrists for comparison of two patients with marked rickets (T M and P J) who received 720 cc of L milk and 720 cc of Y milk respectively (Continued in figs 11, 12 and 13). The figures and letters appearing in the photographs of the roentgenograms give the date the number of days (D) either before (B) or after (A) treatment and the approximate degree of healing in per cent (0 indicates no healing, 25 indicates 25 per cent healing and so on). L patient T M Left thirty days before L milk therapy no healing blood serum calcium 66 inorganic phosphate 38 phosphatase 134 Right one day before L milk therapy no healing blood serum calcium 6 inorganic phosphate 42 phosphatase 146 Y patient P J Left thirty two days before Y milk therapy no healing no blood chemistry done at this time as the parents temporarily refused to permit the patient to remain at the hospital Right one day before Y milk therapy no healing blood serum calcium 72 inorganic phosphate 28 phosphatase 133 One week previously identical figures for calcium and inorganic phosphate were obtained and determinations made at ten and seventeen days after the beginning of treatment also showed practically identical figures for the inorganic phosphate.

unequivocally answered by adopting a plan that was developed by Hartman and one of us⁵ in 1925 after unsuccessfully attempting to determine the relative antirachitic value of cod liver oil quartz lamp and carbon

Fig 11—Roentgenograms for comparison continued from figure 10 L patient T M Left twenty four days after L milk therapy 25 per cent healing blood serum calcium 92 inorganic phosphate 38 phosphatase 072 Right thirty three days after L milk therapy 50 per cent healing blood serum calcium 98 inorganic phosphate 53 phosphatase 094 Y patient P J Left twenty five days after Y milk therapy 25 per cent healing blood serum calcium 92 inorganic phosphate 33 phosphatase 126 Right thirty nine days after Y milk therapy 50 per cent healing blood serum calcium 91 inorganic phosphate 41 phosphatase 152

arc therapy, and that led us to recognize the significance of interrupted and of inadequate therapy in the etiology of infantile rachitic spasmophilia⁶ (secondary low calcium rickets)

The plan just referred to requires that a treatment free period of from three to five weeks precede the administration of the antirachitic agent to be tested in order to be certain that a healing of the rickets has not already begun and, if signs of healing are evident in the roentgenograms, that the healing process responsible for the changes has come to a standstill. Unless one or the other of these conditions is found to be present in the patients studied, no dependence, from the standpoint of scientific accuracy, can be placed on the results of the assay made. Furthermore, it is advisable in order to obtain a dependable quantitative answer once the administration of the antirachitic factor has been started in a suitable case, that treatment be con-

Fig 12—Roentgenograms for comparison continued from figure 11 L patient T M Left fifty five days after L milk therapy 75 per cent healing blood serum calcium 102 inorganic phosphate 56 phosphatase 096 Right sixty six days after L milk therapy 85 per cent healing blood serum calcium 101 inorganic phosphate 59 phosphatase 055 Y patient P J Left fifty three days after Y milk therapy 75 per cent healing blood serum calcium 96 inorganic phosphate 53 phosphatase 141 Right sixty seven days after Y milk therapy 90 per cent healing blood serum calcium 98 inorganic phosphate 59 phosphatase 125

tinued for a period of time sufficiently long to give the antirachitic factor full opportunity to bring about a complete healing of the rickets. Such a period of therapy should be at least twelve weeks long and if necessary, even twenty to twenty-four. If complete healing, as definitely shown by the conditions found in the blood and in the roentgenograms, has been brought

Fig 13—Roentgenograms for comparison continued from figures 10 and 12 L patient T M Left sixty six days after L milk therapy, condition same as shown at right (L) figure 12 Right ninety-one days after L milk therapy 95 per cent healing no blood taken (twenty five days after discharge) Y patient P J Left, sixty seven days after Y milk therapy condition same as shown at right (Y) figure 12 Right eighty-one days after Y milk therapy 95 per cent healing blood serum calcium 94 inorganic phosphate 58 phosphatase 078

about before twelve weeks has elapsed, it will be unnecessary, of course, to continue the observation for twelve weeks. However, when working with minimal rather than with maximal doses of the antirachitic factor it usually will be found necessary to continue the period of therapy, for purposes of observation of the progress made for at least twelve weeks.

The neglect on the part of most authors to observe these essential requirements has been responsible for much confusion and for unnecessary, faulty conclusions regarding the relative value of various antirachitic agents⁷ and also regarding the size of the potent dose. The statements made in the literature with regard to the relative efficacy of cod liver oil and the size of the dose necessary for the cure and prevention of rickets particularly provide an excellent example in point.⁸

The absence of healing or the stationary state of a healing process can be established most dependably by a simultaneous⁹ and sufficiently long study of the calcium, inorganic phosphate and phosphatase levels of the blood serum on the one hand and of the roentgenograms of the bones on the other. The former should be made at intervals of two weeks and the latter at intervals of one week. Furthermore, during such a period of observation it is essential that the antirachitic factor from any other source be prevented from exerting its influence. In checking the potency of a given antirachitic agent, the biweekly periods of blood taking for chemical study may be extended to periods of from three to four weeks' duration as soon as it is evident from the data furnished by the preceding blood chemistry studies and by the weekly roentgenograms that a state of good and progressive healing is present. Occasionally, but only very rarely, crucial situations develop which require repetition of the blood chemistry study after an interval of one week.

In view of the experiences had by us while observing the precautions just outlined, it has been and still is our opinion that the studies based on observations made on infants in outpatient departments or in their homes, where absolute control and study of the blood chemistry are out of the question, are bound to be inaccurate and therefore useless from the standpoint of obtaining a scientifically correct quantitative answer to the question or questions existing in the problem under discussion.

A good illustration of the extent and seriousness of the risk taken by investigators who do not observe the precautions specified is presented by the record of one of the members of the group of twenty-eight infants admitted to the hospital as potential material for use in this study (figs 3 to 7). This is simply one of many examples that we have observed in the past and is identical with the two cases encountered by Kramer and Gittleman¹⁰ in their last study.

While testing the antirachitic potency of various antirachitic agents in the manner described we have at our clinic never seen a rachitic human bone heal, as observed in weekly roentgenograms, unless in the blood serum the level either of the calcium or of the inorganic phosphate or the levels of both began to ascend toward normal, also we have never seen a state of complete

healing established unless normal levels of these substances in the blood serum had been reached previously.

Occasionally, but very rarely, one sees patients whose calcium level will not rise above 9.8 and others whose inorganic phosphate level will remain at 4.8, even though the bone has completely healed and even though the administration of the antirachitic agent has been increased beyond the quantity commonly found to be ample for the establishment of a complete cure in other rachitic patients. A change from one type of antirachitic factor to another, as, for instance, from cod liver oil to sunlight, also fails to bring about a change in these cases. Under these circumstances we have accepted the figures mentioned as representing normal levels for the particular patient and, as a matter of fact the figures 9.8 for calcium and 4.8 for inorganic phosphate are generally accepted as being within the normal zone, although in our own experience the blood serum calcium level has been 10 or above and the inorganic phosphate 5 or above in rachitic infants whose bones have been brought back to normal by the various forms of therapy employed by us.

We therefore attach great significance to regular and frequent determinations of the calcium, inorganic phos-

phate and ideally also of the phosphatase levels in the blood serum and consider them to be the most dependable and really the only totally objective criteria available for the giving of a scientifically correct answer to the question whether or not the metabolic disorder called rickets has ceased to be active and whether or not the bone sooner or later will be completely healed.

As prominent an investigator as Alfred Hess,¹¹ however, has maintained that the presence of a mild form of rickets does not exclude the finding of normal calcium and inorganic phosphate levels in the serum of infants to whom the antirachitic factor was administered in the hope of preventing the appearance of rickets. For this and other reasons, even though on the basis of our own extensive experience we cannot accept this conclusion, we consider it to be wiser, in order to answer clearly the question before us, to use, at least for the present, the curative rather than the preventive method in determining whether or not a given substance at a given dose is adequately antirachitic. We therefore chose for this study to apply the curative method of assay, as has been our custom.

A group of more than seventy supposedly rachitic infants was examined, from which twenty-eight were selected to be hospitalized in order to determine the degree of rickets present and the presence or absence of healing. Of these twenty-eight infants, fifteen were

found to be suitable for the purposes of the study, that is, during the preliminary period of observation varying from a minimum of two weeks to a maximum of four weeks they presented active rickets in a state of nonhealing or of stationary healing. However, only the data collected on thirteen¹² of the fifteen infants chosen for study could be used as one of the fifteen infants suffered in an irregular fashion from anorexia,

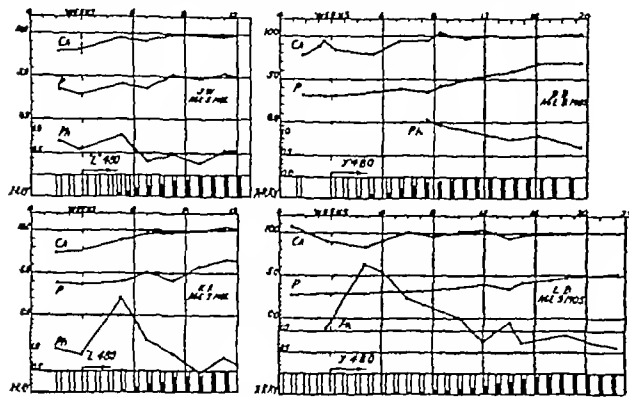

Fig 14—Blood serum calcium inorganic phosphate and phosphatase curves and degree of healing as revealed by roentgenograms for the two patients (J W and K A) receiving 480 cc of L milk for comparison with the condition of two of the patients receiving 480 cc of Y milk (D B and L B). One patient (J W) had mild rickets the other three had moderate rickets. It will be seen that only one roentgenogram of patient D B was taken during the period before treatment this was done because of the presence of pertussis. No healing however occurred during this period as is evidenced by the roentgenograms taken twenty and twenty-eight days later namely at the time of the beginning of treatment and one week later.

vomiting, dyspepsia and fever and a second infant was taken from the hospital to accompany its parents to another city before the investigation had proceeded far enough for the data on this infant to be of value.

The ages of the infants in the various groups and the degree of rickets present, at the time when the feeding of the antirachitic milks was begun are given in table 9. All of the infants were Negroes except C A.

The first two groups of these infants were simultaneously ready for study. Four of these infants were given 720 cc of L milk daily and the other four 720 cc of Y milk daily, as the results of the preliminary curative assays of the liquid milks (as explained in part I) had shown each of them to contain approximately 55 Steenbock rat units per quart. To these milks was added, in the customary manner, lactic acid in the proportion of 5 cc per liter. In addition, each infant received, to meet his caloric and nutritional requirements skimmed milk, 30 cc of orange juice, and carbohydrate in the form of Borchardt's malt sugar in an amount to equal from 6 to 9 per cent of the total quantity of milk ingested daily. Water was offered ad libitum, usually in the form of a 5 per cent solution of corn syrup. The skimmed milk came from the Ohio Agricultural Experiment Station at Wooster (see part I of this paper). The infant subsequently omitted because of anorexia, vomiting, dyspepsia and fever belonged to the 720 cc Y milk group.

As the study of the charts¹³ (figs 8 and 9) and the roentgenograms (figs 10 11, 12 and 13) of these

infants showed both milks at the daily dose of 720 cc to be definitely potent, it was decided also to feed a smaller dose of these milks, namely, 480 cc. a day, and to supplement this reduced quantity of whole milk by an increase in the amount of skimmed milk. Six infants in all were observed while they were fed the smaller amount of the milks being tested. The first two infants available for this group were given the L milk because it was thought probable, from the experience obtained with the 720 cc dose of this milk, that a daily amount of 480 cc would give a positive result, and because a negative result would make unnecessary the testing of the 480 cc dose of the Y milk. A positive result was obtained, and therefore the remaining infants were fed daily 480 cc of the Y milk. More infants were fed the smaller dose of Y milk than of L milk because the healing response of the first two infants fed 480 cc of Y milk was markedly less rapid than that observed in the two infants fed 480 cc of L milk, and because the rickets happened to be somewhat more severe in the former, both infants having a moderate rickets, whereas one of the two infants fed 480 cc of L milk had mild and the other moderate rickets (figs 14 and 15 and table 9). The third and fourth infants fed 480 cc of Y milk also had moderate rickets.

All of the infants studied except three were kept in our wards under identical environmental conditions and protected carefully against the influence of the antirachitic factor in any form other than the milks being tested. The three infants just referred to were cared for in another institution. One of them (D B, fig 14 and table 9) remained there throughout the period of observation, the other two (L B and S H, figs 14 and 15) spent the first part of the period of study there and the last part in our wards, where the larger group was observed. The last two infants while in the other institution were accidentally placed on a covered porch by a nurse on two successive days for a total of six

Fig 15—Blood serum calcium inorganic phosphate and phosphatase curves and degree of healing as revealed by roentgenograms for the two patients (J W and K A) receiving 480 cc of L milk for comparison with the condition of two of the patients receiving 480 cc of Y milk (F S and S H). All except J W had moderate rickets (see also figure 14).

hours. The infants, both Negroes, were completely dressed and were not exposed to direct sunlight or sky light.

This accident occurred during the early part of the period of treatment of these infants at a time when the healing was progressing very slowly. Further prolonged observation did not disclose any discernible influence on the healing process from this accidental

¹² While it is fully appreciated that the total number of rachitic infants studied is small and smaller than we had hoped for, we are convinced that data from even a small number of cases adequately controlled is of much more value than the data from a much larger number of ambulatory and inadequately controlled cases.

¹³ Because of the need for hospital beds, six of the 720 cc dose patients were discharged before complete healing of the bones had been registered in the roentgenograms. However, in all these cases the blood serum calcium and inorganic phosphate levels had been normal for some time. This fact justified the assumption that complete healing would have been established in the roentgenograms had the infants been observed a few weeks longer.

exposure to the daylight of the covered porch and therefore it can be accepted as having been of no significance. In one of these infants (S H) it required 155 days (table 10 and fig 15) and in the other (L B) 144 days (table 10 and fig 14) to bring the blood serum calcium and inorganic phosphate values to normal levels

* Values of 9.8 for calcium and 4.8 for inorganic phosphate considered normal.

While, as stated before, it was accepted by Krauss and Bethke on the basis of their preliminary curative assays that both milks contained an average of 55 Steenbock rat units per quart, their later and final assays required them to conclude, in conformity with the results of their original prophylactic assays of the composite fats, as stated in part I, that there was a decided difference in the antirachitic factor content of the two milks, the L milk, namely, containing an average of 80 rat units per quart and the milk produced by

Corrected on basis of 40 rat units per day

cows fed irradiated yeast (Y milk) an average of 55. As a result the L milk group actually received 60 rat units for each 720 cc and the Y milk group 41, making a practical ratio in the antirachitic factor content of the two milks of 1.5:1 (table 11).

This observation explained the difference established by us between the length of time required by the L milk on the one hand and the Y milk on the other to bring the calcium level to 9.8 and the inorganic phosphate level to 4.8 in the blood serum of our rachitic patients. We had found (table 10), namely, that the L milk according to this method of checking required an average of 42.3 days and the Y milk an average of 61.7, a practical ratio of 1.5:1, which is the identical converse of the ratio between the amount of antirachitic factor present in the two milks as expressed in the form of rat units (table 11). It is evident that the two

ratios virtually cancel each other and place the two milks on an equal plane as far as their antirachitic efficacy is concerned per rat unit content of the antirachitic factor. This interpretation would make the antirachitic efficacy ratio between these two milks 1:1 which corresponds to the results obtained when a theoretical correction is made, on the basis of an intake of 40 rat units per day, for the number of days required to bring the blood serum calcium and inorganic phosphate to normal levels (table 11).

These deductions receive practical confirmation by the actual conditions found in the infants fed a daily amount of 480 cc of the L milk, a dose of the antirachitic factor which is virtually identical in the number of rat units with that received by the group fed 720 cc

TABLE 12—Comparative Time Required to Obtain in the Roentgenogram a 95 Per Cent Degree of Healing in Rachitic Infants Fed L and Y Milks in Amounts of 720 Cc and 480 Cc Daily

of Y milk namely, 41 (table 11). While, as shown in this table, the healing ratio for the 480 cc L group and the 720 cc Y group is somewhat in favor of the former the ratio being 1.125 and the time required 49 and 61.7 days, respectively, to bring the blood serum calcium to 9.8 and the inorganic phosphate to 4.8, it must be appreciated that two of the infants receiving the 720 cc of Y milk were suffering from marked rickets and the third infant from moderate rickets, whereas one of the two infants fed the 480 cc of L milk had a moderate and the other a mild rickets (figs 14 and 15). Therefore, and in view of the fact that the members of the two groups receiving the daily dose of 720 cc of either L milk or Y milk were better balanced, in that both groups contained two patients each with marked rickets and one patient each with moderate rickets (figs 8 and 9), we must conclude that

TABLE 13—Average Comparative Time Required to Obtain Blood Serum Phosphatase Level of 0.9 in Rachitic Infants Fed L and Y Milks in Amounts of 720 Cc and 480 Cc Daily

Milk and Amount	Average Number of Days
720 cc. L milk	34
720 cc. Y milk	59
480 cc. L milk	41.5
480 cc. Y milk	136.5

the efficacy ratio between the two milks of 1:1 is closer to the real efficacy ratio than is 1.125. The fourth member of the Y group had to be discarded, as stated before.

The same reasoning and interpretation can be used in the consideration of the data obtained by the determinations of the blood serum phosphatase levels (table 11).

How nearly equal is the therapeutic efficacy of the antirachitic factor in a daily dose of from 41 to 40 rat units when given in the form of 720 cc of Y milk on

the one hand and in the form of 480 cc of L milk on the other is clearly shown by the very close parallelism of the calcium, inorganic phosphate and phosphatase blood serum curves of the rachitic infants so treated, as presented graphically in figures 16, 17 and 18

The data established on the basis of an evaluation of the degree of healing produced in the bones of the infants fed the 720 cc daily doses of the milks, as registered by the roentgenograms, speak in favor of a

Fig. 16—Blood serum calcium curves in patients receiving 480 cc of L milk and 720 cc of Y milk

superiority of the Y milk over the L milk (tables 11 and 12). However because of the subjective nature of this method of evaluation¹⁴ and also because of the contradictory evidence presented by the data found through the study of the phosphatase levels in the blood serum (tables 11 and 13) which probably indicate more accurately the point at which the bone has actually been completely healed we are of the opinion that the observations as registered in the tables regarding the degree of bone healing are less dependable and therefore are of secondary importance and should not be used to offset the answers obtained by the purely objective method of observing the course of the return of the blood serum calcium, inorganic phosphate and phosphatase to normal levels.

A comparison of the data obtained in the group fed 480 cc of L milk (40 Steenbock rat units) on the one hand and the group fed 480 cc of Y milk (27.5 Steen-

Fig. 17—Blood serum inorganic phosphate curves in patients receiving 480 cc of L milk and 720 cc of Y milk

bock rat units) on the other (figs 14 and 15 and tables 10, 12 and 13) shows the latter to be markedly inferior in antirachitic potency. It required an average of 118.3 days to bring the blood serum calcium and inorganic phosphate to normal levels in the group of rachitic

14 The method consists in judging the degree of progress on a percentage basis by very carefully comparing the entire series of weekly roentgenograms in both directions, namely from the first roentgenogram taken after admission to the last one taken before discharge and vice versa. To take an individual roentgenogram by itself and to rate the signs of healing present as being indicative of active healing and of a definite percentage of active healing is of course not justified and is manifestly entirely different from the plan that we have followed.

infants fed Y milk and receiving 27.5 rat units daily, and only forty-nine days in the group fed L milk and receiving 40 rat units daily. It is our opinion that this marked difference in the antirachitic potency between 480 cc of L milk and 480 cc of Y milk is due to the fact that the number of rat units administered daily to the infants receiving the Y milk, namely, 27.5, probably represented for these infants close to the lowest amount of the antirachitic factor that would bring about complete healing even after a prolonged administration and is, in other words, we feel, a so-called borderline dose whereas the 40 rat units received by the infants taking the 480 cc of L milk represented a dose decidedly above this level. For these reasons it is our opinion that a comparison between the results obtained with these two groups of rachitic infants is not justifiable.

COMMENT

It will be recalled that recently first Hess and Lewis¹⁵ and later Kramer and Gittleman¹⁶ studied the relative antirachitic efficacy of the two types of antirachitic milks evaluated by us. The latter authors used the same method of approach as was employed by us except that they did not continue to observe the infants for as long a time as we did after instituting therapy. Hess and Lewis also used the curative method of assay but

Fig. 18—Blood serum phosphatase curves in patients receiving 480 cc of L milk and 720 cc of Y milk

their method of study differed in many important respects from our own and from that of Kramer and Gittleman in that (1) the clinical material was ambulatory, (2) no preliminary treatment-free period was observed, (3) no blood chemistry studies were made and (4) the only criterion for judging the efficacy of the antirachitic milks was the degree of healing found present four weeks after the beginning of treatment. Hess and Lewis¹⁵ also studied the antirachitic potency of viosterol and of cod liver oil. The data for the latter material, however, do not appear in the table embodying the results obtained with the other antirachitic agents. The method of study used by Hess and Lewis is bound to bring forth data and conclusions that are liable to be uncertain if not distinctly erroneous, and this probably is the principal reason why our conclusions coincide with those reached by Kramer and Gittleman rather than with those presented by Hess and Lewis.

Although we did not include in our studies a simultaneous evaluation of the antirachitic efficacy of cod liver oil, we must, on the basis of published¹⁶ and unpub-

lished data of our own also disagree with Hess and Lewis in their conclusions regarding the size of the dose necessary to insure the prevention of rickets and regarding the efficacy ratio between cod liver oil and irradiated milk. According to Hess's figures this ratio is 6:1 whereas ours would justify a ratio no greater than 2:1 and probably would establish it at or very close to 1:1. We have seen rickets prevented

Kramer and Gittleman¹⁰ in their last contribution, namely, that vitamin D milk is our most effective anti-rachitic agent. We are of the opinion that more work must be done before this conclusion can be accepted as being correct.

CONCLUSIONS

1 Thirteen rachitic infants, after a preliminary treatment-free observation period during which the activity of the rachitic process was established, were divided into groups that were fed 720 cc or 480 cc daily doses of cow's milk made antirachitic either by irradiation or by feeding irradiated yeast to cows. The infants were housed in hospital wards or rooms. Roentgenograms were taken weekly and determinations of the calcium inorganic phosphate and phosphatase levels in the blood serum were made usually every two weeks and only occasionally at intervals of one or three weeks.

2 On the basis of the data collected in this study, it is concluded that there is for rachitic infants no practical difference in antirachitic efficacy between cow's milk made antirachitic on the one hand by irradiation and on the other by feeding cows irradiated yeast, when the same amount of the antirachitic factor is administered as represented by an identical number of Steenbock rat units per day. If, however, there is actually a

Fig 19—Illustration of the effectiveness of a daily dose of less than 1 cc of cod liver oil in the prevention of rickets when administered in the form of straight cod liver oil over a period of twenty nine weeks in a full term normally growing infant as established by normal roentgenograms and by normal blood serum calcium and inorganic phosphate curves.

in rapidly growing infants receiving daily not more than 1 cc of cod liver oil. Two examples are presented in figures 19 and 20, taken from a report made by one of us in 1927.¹⁷ Yet Hess and Lewis advise a daily intake of 8 cc to assure adequate protection. The cod liver oil used by us probably contained 30 units per gram or 27.5 per cubic centimeter, a figure that is identical with the 27.5 present in the 480 cc dose of Y milk, which was ample to bring the calcium and inorganic phosphate levels to normal after an average of 118 days. In other words, it seems clear that there must be another reason for the disparity existing between the experience of other authors and of ourselves and associates than a difference in the antirachitic value of the agent administered.

We are inclined to believe that the real reason is the difference in the methods used in checking the appearance and disappearance of the rickets in human infants. We expect to present our own data on the matter of cod liver oil dosage in the near future.

In our records we also find that we obtained healing of severe human rickets at a greater speed than that established by us in this study for the 720 cc daily dose of L milk when we were feeding rachitic infants 25 Gm of cod liver oil in the form of 720 cc of Protein S M A.¹⁸ We therefore feel that we cannot in view of these and our other experiences at the present time subscribe to the statement made by

Fig 20—Illustration of the effectiveness of a daily dose of less than 1 cc of cod liver oil in the prevention of rickets when administered in the form of Protein S M A over a period of eighteen weeks in a rapidly growing premature infant as established by normal roentgenograms and by normal blood serum calcium and inorganic phosphate curves

slight superiority in the antirachitic effectiveness of one milk over the other, it exists in our opinion, in favor of the irradiated milk.

3 The antirachitic factor in both milks in an amount assayed to equal 40 Steenbock rat units per day was able to produce satisfactory healing in the blood in from 49 to 617 days and in the bone in from 105 to 11 weeks.

1 Gerstenberger ⁶
18 Gerstenberger H J Unpublished data

4 The antirachitic factor in the yeast milk in an amount assayed to equal 27.5 Steenbock rat units per day also was able to bring about satisfactory healing in the blood and in the bone. However, the period of time required to bring about this result in the blood was on an average 118 days (from 74 to 155 days) and in the bones on an average 21.2 weeks (from 16 to 24 weeks).

It is believed, therefore, that for the rachitic infants tested in this study the dose of 27.5 Steenbock rat units per day was very close to the actual minimum amount required for the ultimate healing of the active rickets.

5 Published and unpublished data of ourselves and our associates concerning the antirachitic effectiveness of cod liver oil warrant the use of caution in formulating for rachitic infants conclusions regarding the efficacy ratio of cod liver oil on the one hand and of the antirachitic milks on the other. Further data must be presented before the antirachitic effectiveness of cod liver oil for the human infant can be accepted to be decidedly inferior to that of cow's milk made antirachitic by irradiation or by feeding irradiated yeast to cows.

Clinical Notes, Suggestions and New Instruments

ULCERATIVE VULVITIS AND STOMATITIS OF ENDOCRINE ORIGIN

A. J. ZISERMAN, M.D., PHILADELPHIA

The coexistence of nonvenereal ulcerative lesions of the mouth and genitalia was originally reported by Neumann.¹ A comprehensive review of this rare condition was recently presented by Wien and Perlstein² who collected a total of twenty-nine cases from the literature and reported in addition a personal case, which was the first to be recorded in this country.

There has been considerable variation of opinion regarding the etiology of this condition. One of the theories attributes the ulcerative lesions to an angioneurosis caused by ovarian dysfunction.³ Although the usual coexisting menstrual disorder gives plausibility to this belief there has been no attempt at a therapeutic test to verify this theory.

This case is reported because the therapeutic result obtained points to a possible endocrine etiology of the disorder and also because of the rarity of the condition.

M. M., a woman aged 23 seen in July 1932 complained of periodically recurring ulcers of the mouth and occasionally the vulva. The time of appearance and duration of these lesions was definitely associated with the onset and termination of her menstrual periods. The latter were irregular, coming at intervals of from four to six weeks, and were scanty in quantity. Otherwise the previous medical history was irrelevant.

The ulcers were small, varying in size from 2 to 5 mm in their longest dimension and covered with grayish pellicles which left a raw bleeding base when removed. They were usually situated on the mucosa of the lower lip, buccal surfaces, the pharyngeal wall and the sides of the tongue. Some of the ulcers were confluent. No scars were noted on the buccal mucosa, and the cervical glands were definitely enlarged. The lesions of the mouth usually caused an aching pain, which became stablike in character on eating or drinking. The vulvar lesions when present had an appearance identical with those in the mouth.

2. Wien, M. S. and Perlstein, M. C. Ulcers Vulvae Acutae Associated with Lesions of the Mouth. J. A. M. A. 98: 461-466 (Feb. 9) 1932.

3. Schugt, P. Das Uleus Vulvae Acutum (Lipshutz) und seine Aetiology. Zentralbl. f. Gynak. 49: 2180-2185 (Sept. 26) 1925.

Smears taken from the ulcerated areas showed numerous leukocytes, a few gram positive diplococci, and a few fusiform bacilli. On culture, viridans streptococcus, viridans flava and an actinomycotic form were isolated.

The lesions first appeared in 1922 and were diagnosed at that time as "stomach ulcers." They were then limited in extent and occurred at intervals of from three to four months. During the last five years the ulcers recurred regularly with each period and became more extensive in their distribution, involving the vulva more frequently. The lesions always appeared three days before the expected menstrual flow, lasting throughout the period and disappearing at about the third day after the cessation of the flow.

Despite negative Wassermann reactions of both the blood and the spinal fluid a clinical diagnosis of syphilis was made, for which the patient was treated over a period of three years without any appreciable change in the condition. An intervening pregnancy during 1931 prevented the usual recurrence of the oral and vulvar ulcers, but premature termination of the pregnancy at five months was followed by reappearance of the lesions with the return of her periods.

The striking association of the appearance and disappearance of the lesions with the premenstruum and the postmenstruum was highly suggestive of an endocrine dysfunction as an etiologic factor. The accompanying chart shows the probable concentrations of estrogenic substance and anterior pituitary at the various stages of the menstrual cycle.⁴

Since the ulcers appear at the premenstrual period when estrogenic substance is at its greatest concentration and disappear at the postmenstruum when the minimum amount of follicular hormone is present, it follows that a deficiency of this hormone is probably not the etiologic factor. On the other hand, it may be noted that the lesions are present during the stage when the pituitary normally lessens its function and that their absence is coincident with the interval when anterior pituitary reaches its maximum concentration. The possibility of a failure of luteinization primarily or secondarily to a pituitary deficiency was another possible association. Likewise, during pregnancy, when the anterior lobe attained its highest degree of activity, there was a spontaneous disappearance of the ulcerations.

The delay in the periods and the associated genital hypoplasia were further suggestive of a pituitary deficiency. On this assumption, I believed that therapy should be directed either to combat the supposed deficiency or to stimulate the anterior pituitary lobe to increased function. The patient was therefore given subcutaneous injections of Berkefeld filtered ether extracted urine of patients from four to five months pregnant. Fifty rat units of anterior pituitary was administered every other day. Prior to the institution of organotherapy, there had been no period of spontaneous remission of the ulcerations except during pregnancy. Prompt improvement was noted during the first period following the institution of this treatment. Complete relief from ulcerations was obtained over a period of three months, including one month subsequent to the withdrawal of the treatment. As this mode of treatment was purely substitutive, roentgen stimulation of the anterior lobe was administered in the hope of correcting the primary cause of this disorder and obtaining a more lasting improvement. Following roentgen therapy the patient was free from ulcerations for a period of four months.

She reported a mild recurrence in the fourth month after roentgen treatment. Since then no lesions have appeared and the menses have become regular and normal in quantity and duration.

I DIABETOGENIC SUBSTANCE

Numerous observations made both in the clinic and in the laboratory are to be found in the literature of the last few years which indicate either directly or indirectly that the pituitary gland may influence definitely the metabolism of both carbohydrate and fat, for this reason there has been a growing conviction that the pituitary has some endocrine relationship with the pancreatic islets or their secretion.

Borchardt¹ noted the frequent occurrence of glycosuria in acromegaly, and this was confirmed by Goetsch, Cushing and Jacobson.² More recently Houssay³ and Eidelsberg⁴ have called attention to the frequent occurrence of diabetes in cases of acromegaly.

Glycosuria and hyperglycemia have been produced in normal animals by the use of anterior lobe extracts (Johns, O'Mulvenny, Potts and Laughton,⁵ H. M. Evans,⁶ Baumann and Marine,⁷ Houssay and his collaborators,⁸ Lucke,⁹ E. I. Evans¹⁰ and Barnes and Regan.¹¹)

¹¹ Barnes B O., and Regan J F. Relation of Anterior Pituitary to Carbohydrate Metabolism. *Endocrinology* 17: 522-528 (Sept-Oct) 1933.

The great importance of the pituitary gland in relation to carbohydrate metabolism has been generally recognized since the publication by Houssay and his collaborators of their experiments on the effect of removal of the hypophysis on pancreatic diabetes of toads and dogs. This work, which is now a classic, demonstrated most conclusively that the cardinal symptoms of pancreatic diabetes—glycosuria, hyperglycemia and acidosis—were considerably ameliorated when the hypophysis was removed from the totally pancreatectomized animal. Houssay's work has received ample confirmation (Barnes and Regan,¹¹ Regan and Barnes,¹² Lucke^{9b} Kutz and his associates¹³).

The Houssay dog (completely pancreatectomized and hypophysectomized) is a most sensitive test object for the diabetogenic effect of pituitary extracts.

It was established by the Houssay school that the diabetogenic substance is an anterior lobe product, that it is not the thyrotropic hormone, since the effect can be obtained in thyroidectomized Houssay animals, and that it occurs regularly in active growth hormone extracts.

It should be emphasized that the hypophysectomized, pancreatectomized dog is not entirely free from the symptoms of pancreatic diabetes. Such an animal may, however, live for months without specific treatment, but the fatal issue is inevitable since it gradually becomes more and more undernourished and with the progressive loss in weight it becomes extremely cachectic and dies. Houssay¹⁴ reports that such animals survived six months while one animal in our laboratory lived for a period of nine months.

The blood sugar level of the untreated Houssay dog undergoes extremely wide fluctuations. The fasting level may be under 100 mg per hundred cubic centimeters, but following feeding values up to 300 mg per hundred cubic centimeters may be observed. Glycosuria may be seen for the few hours following feeding and the total sugar excretion may on this account be very little. Ketonuria is reduced to a minimum. The injection of even small amounts of anterior pituitary extract results in elevation of the blood sugar level, a greatly increased glycosuria, and a return of ketonuria.

The Houssay animal, like the hypophysectomized animal, is very sensitive to insulin. Treatment of the former with both anterior pituitary extract and insulin can be carried out with care and the animal is then comparable to the ordinary pancreatectomized dog maintained on insulin. The diabetogenic substance has therefore been looked on as having an anti-insulin action. Insulin hypoglycemia is decreased in normal animals by the diabetogenic substance, but the antagonistic effect between the two principles is more readily demonstrated in the hypophysectomized, pancreatectomized animal (Houssay,^{6d} Lucke⁹).

The literature on anterior pituitary physiology as far as it bears on diabetes falls into two divisions: one dealing with the relationship of the gland to carbohydrate metabolism, and the other to fat metabolism. The terms carbohydrate hormone and fat hormone have been used rather freely. This is unfortunate since in large

measure the anterior lobe function and the pancreatic islet function are more or less antagonistic one to the other. The term "fat metabolism hormone" may be justified ultimately, but for the present the term "ketogenic principle" is more suitable in my opinion. In the following pages I shall refer to the blood sugar raising principle as "anterior pituitary blood sugar raising hormone," and to the ketogenic substance as "anterior pituitary ketogenic hormone."

EFFECT OF HYPOPHYSECTOMY ON BLOOD SUGAR AND SUGAR EXCRETION

Some authors found subnormal blood sugar values in the hypophysectomized dog (Kobayashi,¹⁵ Re¹⁶ Koster and Geesink,¹⁷ D'Amour and Keller,¹⁸ Lucke and his co-workers¹⁹) and in the rabbit (Fujimoto,²⁰ Corkill, Marks and White²¹). However it seems to be well established today that the blood sugar of fed hypophysectomized animals is normal and that hypoglycemia ensues only after fasting. This has been shown by Zwarenstein and Bosman²² in amphibia by Orias²³ in fishes, and by Houssay and his collaborators²⁴ and Braier²⁵ in the dog. The effect of fasting on the blood sugar of the hypophysectomized animal is very marked and often leads to fatal hypoglycemia in the dog if dextrose is not administered in time (Braier,²⁶ Lucke and his associates²⁷). Similar observations have also been made on hypophysectomized monkeys in our laboratory. We have frequently observed severe hypoglycemic symptoms if such animals refuse to eat for some time. The blood sugar in one of these was only 27 mg per hundred cubic centimeters and the animal was quite cold and unconscious to such a degree that we could lay its femoral artery free without evoking a reflex motion. The femoral artery showed no pulsation and the heart beat and respiration were barely perceptible. At this time we administered concentrated dextrose solution into the femoral vein the curative effect of which was so dramatic that the hitherto prostrate animal jumped up on the table during the injection and took food within a few hours.²⁸ We have also repeatedly seen similar recoveries in hypophysectomized

fasted dogs. This marked tendency of the hypophysectomized animal to develop hypoglycemia after fasting is not due to accompanying tuber injury, for tuber injury in itself does not produce this change, according to Houssay.^{24a} D'Amour and Keller,¹⁸ however, state in a more recent publication that chiasmal lesions also tend to lower the blood sugar in the dog.

The dextrose tolerance curve of hypophysectomized dogs is not different from that of normal control animals, according to Camus and Roussy²⁹ and to Houssay.^{24b} Lucke and his collaborators,¹⁹ however, in a more recent publication state that the rise in blood sugar after dextrose administration is higher after hypophysectomy in the dog. In the rabbit, Fujimoto²⁰ found an increased dextrose tolerance after complete hypophysectomy, and this has been confirmed on partially hypophysectomized rabbits by Sakamoto and Saito.³⁰

In the toad, increased tolerance has been found by Zwarenstein and Bosman.²²

The apparent discrepancy between these observations may possibly be explained by the presence of accompanying tuber injuries and by the difference in the nutritional condition of the animal.

EFFECT OF INSULIN ON BLOOD SUGAR AFTER HYPOPHYSECTOMY

Hypophysectomized dogs are extremely sensitive to insulin. Doses that would be tolerated without any difficulty by normal animals will often lead to fatal hypoglycemia in the absence of the pituitary (Houssay and Magenta³¹ Kobayashi,¹⁵ Lucke and his collaborators¹⁹). The same is true of hypophysectomized toads (Houssay and Potick³²) and rabbits (Fujimoto,²⁰ Corkill and his associates²¹).

Posterior lobe extracts, especially those containing the oxytocic factor, antagonize these effects of insulin according to Houssay and Magenta^{31a} and to Houssay and Potick.³²

EFFECT OF HYPOPHYSECTOMY ON THE RESPIRATORY QUOTIENT

According to Houssay and his co-workers,³³ the respiratory quotient is normal in hypophysectomized toads. In the dog, there is no change in the respiratory quotient, according to Gaebler.³⁴

EFFECT OF HYPOPHYSECTOMY ON RESPIRATORY QUOTIENT AFTER PANCREATECTOMY

It is of considerable interest that the respiratory quotient of hypophysectomized and pancreatectomized dogs rises after the administration of dextrose, as has been

shown by Houssay and Biasotti,³⁵ this finding suggests that the inhibition of carbohydrate oxidation in pancreatectomized animals is not merely the result of a lack of insulin but is also due to the presence of the hypophyseal hormone

LIVER GLYCOGEN IN THE HOUSSAY DOG

We have found that Houssay dogs are able to store liver glycogen 18 per cent was found in one instance and 165 per cent in another

EFFECT OF HYPOPHYSECTOMY ON THE BLOOD SUGAR AFTER PANCREATECTOMY

The discovery of Houssay that pancreatic diabetes is relieved by hypophysectomy has been established on various species of toads by Houssay and his co-workers³⁰ and by Braier³ in fishes by Orias²³ in the snake by Houssay and Biasotti^{30c} and in the dog by Houssay and Biasotti³⁸ and by Lucke and his co-workers.⁴⁰

It is remarkable that lesions of the tuber cinereum region have the same inhibitory effect on the development of pancreatic diabetes in toads as hypophysectomy and that here again hypophyseal implants have a diabetogenic action, although the animal's own pituitary has not been removed (Houssay and Biasotti⁴⁰). The pancreatic diabetes of the dog (Houssay and Biasotti²⁶) and of the fish (Orias²³), however, is not relieved by such brain lesions

The increased insulin sensitivity of the hypophysectomized animal is very marked in dogs, even if the pancreas is also removed (Regan and Barnes⁴¹)

EFFECT OF EPINEPHRINE ON THE BLOOD SUGAR OF HYPOPHYSECTOMIZED ANIMALS

In the dog, Aschner⁴² found a decrease in epinephrine hyperglycemia after hypophysectomy, while Kobayashi,¹⁶ Re,⁴³ and Lucke with his collaborators¹⁰ found an increased hyperglycemia under the same conditions. These results may possibly be explained by the experiments of Braier,⁴⁴ who found that epinephrine hyperglycemia is increased in the fed and decreased in the fasted dog. In rabbits, Fujimoto²⁰ and Corkill, Marks and White²¹ report decreased epinephrine hyperglycemia after hypophysectomy

In the toad epinephrine hyperglycemia is decreased after hypophysectomy, but not after tuber lesions without hypophysectomy, hypophyseal implants restore the

reaction to epinephrine to normal (Houssay and Benedetto⁴⁵)

EFFECT OF OTHER HORMONES ON THE BLOOD SUGAR AFTER HYPOPHYSECTOMY

The hyperglycemia produced by thyroxine is not as marked in partially hypophysectomized dogs as it is in normal animals (Lucke and collaborators⁴⁰)

EFFECT OF TOXINS ON BLOOD SUGAR AFTER HYPOPHYSECTOMY

While Aschner⁴² found no change in phlorhizin glycosuria in hypophysectomized dogs, Houssay and Biasotti⁴⁷ observed that the sugar excretion in phlorhizin treated dogs is less pronounced after the hypophysis has been removed and that the blood sugar falls to much lower levels. They conclude that glycogenesis from endogenous proteins must be impaired under these conditions.⁴⁸ Similarly, in the hypophysectomized toad, di Benedetto⁴⁰ found phlorhizin glycosuria to be much less pronounced than in the normal animal. Pituitary implants increase the glycosuria under these conditions. A similar although less marked inhibition of the glycosuria may be produced in the toad by tuber injury (di Benedetto^{40a})

Morphine leads to unusually little hyperglycemia in hypophysectomized toads, unless pituitary implants are given (di Benedetto⁴⁵)

EFFECT OF HYPOPHYSECTOMY ON BLOOD SUGAR DURING AVITAMINOSIS

While normal dogs show marked hyperglycemia when kept on a vitamin B deficient diet, no rise in blood sugar is observed in B deficient hypophysectomized animals (Braier⁴⁰)

EFFECT OF HYPOPHYSECTOMY ON THE GLYCOGEN CONTENT OF THE LIVER

The glycogen content of the liver decreases after hypophysectomy in the toad, but this decrease may be inhibited by the administration of alkaline pituitary extracts (Houssay and his co-workers²¹). Epinephrine does not decrease the liver glycogen in the hypophysectomized toad (Houssay and Benedetto⁴⁵). Nakamura⁵² found that the liver glycogen is very low even in partially hypophysectomized rabbits, Corkill, Marks and White²¹ also noted low liver glycogen in some of their hypophysectomized rabbits. In the dog, the glycogen content of the liver after hypophysectomy is

not markedly different from normal (Houssay,^{24b} Aschner⁵³)

EFFECT OF HYPOPHYSECTOMY ON THE GLYCOGEN CONTENT OF MUSCLE

In the toad, the glycogen content of the muscle is slightly subnormal after hypophysectomy, and the glycogen content of the entire animal is also decreased (Houssay and his collaborators³³), but this apparently is not a regular finding since these authors found no change in muscle glycogen in the toad in other experimental series.⁴¹ In partially hypophysectomized rabbits the liver glycogen of which was subnormal the muscle glycogen showed no change (Nakamura⁵²). In the dog, no change in muscle glycogen has been observed (Houssay and his co-workers^{24b}).

CHEMISTRY

According to Houssay and his collaborators⁵⁴ hypophyseal tissue maintains its activity on carbohydrate metabolism when stored in acetone. The active principle is soluble in water and in 60 per cent alcohol, it is insoluble in absolute alcohol, ether, acetone, benzene and chloroform. It is destroyed by boiling and does not pass through ultrafilters. It is easily adsorbable.

In a more recent communication Houssay and his collaborators^{30c} state that they have also been successful in preparing potent extracts of the blood sugar raising principle from human urine. The procedure used was the following: Five hundred grams of kaolin is added to 500 cc of urine. The mixture is allowed to stand at room temperature for several hours. After that the kaolin is eluted with dilute alcohol. The fraction thus obtained is dissolved in water. Particularly large quantities may be obtained from the urine of diabetic patients. These extracts increase the glycosuria of the hypophysectomized and pancreatectomized dog.

The blood sugar raising principle is present in the pituitary of toads, frogs, fishes, birds and man (Houssay and Biasotti^{54a}). It has been shown by the Houssay school that this hormone is not identical with the pressor or oxytocic factors, and it is absent in the posterior lobe of the hypophysis. It is also well established that this hormone is not identical with the thyrotropic principle since, as will be seen later, it is active in thyroidectomized animals. Its chemical properties are, however, very similar to those of the growth hormone, and it is for this reason that Lucke⁵⁵ has not been able to separate it from the latter fraction. The publications of H. M. Evans, and his co-workers⁵⁶ and of Houssay and his collaborators^{5a} show also that growth hormone extracts are usually very rich in the blood sugar raising factor. According to Lucke,^{55a} the hormone cannot be identical with the ketogenic factor, since it is not ultrafiltrable as is the latter.

EFFECT OF HYPOPHYSECTOMY ON GLYCOSURIA

The original glycosuria, which is often observed during the first few days after the removal of the pituitary, reminds one of the sugar excretion produced

by experimental tuber lesions. It has often been observed by Houssay and his co-workers^{24b} and by others, but the fact that tuber injury in itself will produce transient glycosuria, even after the pituitary has been removed previously, shows that this phenomenon is due to the lesion of the nervous tissue (Canus and Roussy⁵⁷).

Houssay expresses the view^{24a} that even the "diabetic glycosurias," such as may be produced by hypothalamic lesions, are merely due to interference with the innervation or vascularization of the pituitary.

EFFECT OF THE PITUITARY BLOOD SUGAR RAISING PRINCIPLE ON BLOOD SUGAR AFTER INSULIN

Insulin hypoglycemia is decreased in normal dogs if the blood sugar raising factor is administered at the same time (Houssay^{5d} Lucke^{5a}). The inhibiting effect of this principle on insulin is still more marked if the two hormones are tested on pancreatectomized animals (Lucke^{5b}).

The insulin resistance of hypophysectomized and pancreatectomized dogs increases after the administration of the blood sugar raising hormone (di Benedetto⁵⁸), similar observations have been made by this author⁵⁹ on the hypophysectomized dog, the pancreas of which was not removed.

The glycosuria of pancreatectomized toads is greatly increased after administration of the blood sugar raising hormone (Houssay and Biasotti^{54a}). In both pancreatectomized and hypophysectomized toads, Campos and his co-workers⁶⁰ were able to produce glycosuria with anterior pituitary extracts.

EFFECT OF THE BLOOD SUGAR INCREASING FACTOR ON BLOOD SUGAR AND GLYCOSURIA AFTER ADMINISTRATION OF VARIOUS TOXINS

The blood sugar raising principle increases morphine hyperglycemia in the normal dog, according to Houssay and di Benedetto⁶¹.

Phlorhizin glycosuria is increased in hypophysectomized toads after the administration of pituitary implants (di Benedetto^{40a}) and the same is true in hypophysectomized dogs, according to Houssay and his co-workers^{47c} after administration of anterior pituitary extracts. Under these conditions ketonuria also appears. In normal fasting dogs, however, phlorhizin glycosuria is decreased after administration of the pituitary factor.

EFFECT OF ANTERIOR PITUITARY-LIKE GONADOTROPIC FACTOR ON BLOOD SUGAR

Various authors have reported that the hypophyseal like gonadotropic factor increases the blood sugar (Eidelsberg,⁶² Böhm⁶³) or decreases the sugar tolerance curve without having any direct effect on the blood

sugar (Snoeck⁶⁴) while Elek⁶⁵ has observed more or less irregular effects on the blood sugar after administration of this principle. Dingemans and Kober⁶⁶ however, showed that the blood sugar raising effect of pituitary-like gonadotropic preparations is not due to the gonadotropic substance itself but to some accompanying impurity. Houssay^{70c} saw no effect on the blood sugar after administration of this gonad-stimulating principle.

CLINICAL OBSERVATIONS CONCERNING THE EFFECT OF PITUITARY ON CARBOHYDRATE METABOLISM

Recently Lucke⁶⁷ studied the effect of pituitary on carbohydrate metabolism and found frequently high fasting blood sugars in acromegaly. The hypoglycemic phase after the administration of dextrose and epinephrine was decreased and there was decreased sensitivity to insulin. On the other hand in a hypopituitary dwarf the blood sugar was low, there was increased sugar tolerance and increased sensitivity to insulin. The anterior pituitary blood sugar raising principle increased the fasting blood sugar in this dwarf. The same author found that thyroxine hyperglycemia may be increased by the simultaneous administration of the pituitary factor.⁶⁸ Wilder⁶⁸ observed cases of hypopituitarism in human beings with severe hypoglycemic attacks that were fatal if sugar was not given. One should mention however cases reported by Kenyon⁶⁹ and Strecker⁷⁰ in which hyperglycemia was observed although clinical signs of hypopituitarism seemed to indicate a decrease in pituitary function.

A very interesting case relevant to this question has been reported by Hertz,⁷¹ who observed marked symptoms of Gierke's disease in a pituitary dwarf and called attention to the possible interrelationships between the pituitary and the so-called glycogen storage disease as described by Gierke. In this condition there is a marked increase in liver glycogen combined with acetonuria. If this condition should really be associated with pituitary malfunction, it would most likely be the result of an overproduction of the ketogenic rather than of the blood sugar raising principle.

THE THEORY OF ACTION OF THE BLOOD SUGAR INCREASING PRINCIPLE

Lucke⁷² believes that the blood sugar increasing principle acts on the nervous centers of carbohydrate metabolism and through these centers influences the

hormone production of the adrenals. He found that the blood sugar raising hormone had no effect on blood sugar after adrenal denervation. It was also ineffective, according to the same author, in adrenalectomized dogs.⁷³ Houssay and Biasotti,^{70e} however, obtained different results, since they found this principle active after the extirpation of the adrenals, the testes or the thyroid. Even complete evisceration did not influence its effect to any extent, as long as the liver was not removed. Therefore these authors conclude that only the liver is absolutely essential for the action of this hormone. Campos and his co-workers⁶⁰ observed, on the other hand that the decrease in blood sugar and muscle glycogen of hepatectomized toads is retarded by anterior lobe implants.

Although Barnes and Regan¹¹ thought, on the basis of preliminary experiments, that thyroidectomy might inhibit the effect of this hormone on the blood sugar, Houssay and his co-workers,⁷⁴ as already mentioned, found the sugar increasing principle to be active in thyroidectomized animals, and Lucke⁷⁵ has obtained similar results. It seems, therefore, that the action of this hormone is independent of the thyroid and thus fraction must be different from the so-called thyrotropic hormone. This view is substantiated by the experiments of Lucke and his co-workers.⁴⁰ Furthermore, Barnes, Regan and Nelson⁷⁶ have shown that estrogenic substance may decrease blood sugar in pancreatectomized animals, they interpreted this finding as an inhibition of pituitary function by the estrogenic principle.

As already mentioned, the blood sugar raising hormone is present in the urine, according to Houssay and Biasotti,^{70e} Houssay and his co-workers^{8b} have also demonstrated some activity occasionally in muscle and thyroid extracts. Traces are also present in the placenta.^{64b}

A remarkable feature about the action of the blood sugar increasing factor is that it raises the blood sugar only after a considerable period of latency (Houssay^{8d}). However, if the hormone is introduced directly into the spinal fluid its effect is instantaneous, according to Lucke,^{7b} this author interprets this observation as an additional proof of his view that it acts directly on the nervous centers.

THE KETOGENIC PRINCIPLE

Burn and Ling⁷⁷ showed that the acetone body excretion of rats kept on a butter diet is greatly increased after the administration of anterior pituitary preparations obtained by extraction with tenth normal sodium hydroxide. Later, Hoffmann and Anselmino⁸ reported experiments showing that pituitary extracts may lead to an increase in the ketone body content of the blood. They think that this effect is produced by a special hormone. Their results have been confirmed by

Magistris,⁷⁹ Funk and Zefirow,⁸⁰ Boenheim and Heimann⁸¹ and others. The name "fettstoffwechselhormon" (fat metabolism hormone) has been suggested by Hoffmann and Anselmino,⁷⁸ while Magistris calls this substance "orophysin."⁷⁹ In the American literature the name "ketogenic hormone" is generally used.

CHEMISTRY OF THE KETOGENIC FACTOR

As previously mentioned, the first attempts to isolate a ketogenic fraction from the pituitary were made by Burn and Ling,⁷⁶ who used alkaline extraction. Further data concerning purification were published by Magistris,⁸² who stated that the blood acetone raising fraction may be obtained by aqueous extraction of pituitaries that have been stored in acetone. The method he uses is the following: Acetone powder of pituitary glands is extracted with water for two days, then the watery suspension is centrifugated and the supernatant fluid is used after the addition of chlorbutanol, which is added as an antiseptic. According to Magistris, the active substance is ultrafiltrable and dialyzable. It is insoluble in absolute alcohol, ether and chloroform, and soluble in dilute alcohol and water. It is easily destroyed by heat, and solutions that have been kept at 60 C for from ten to fifteen minutes or boiled for from three to five minutes are inactive. It is not damaged by hundredth normal acid or alkali, it is adsorbable to silica gel but not to charcoal kaolin or talc. It may also be obtained from the euglobulin fraction of serum.

According to Funk⁸³ it is present in the urine of men and women and may be extracted from this source by shaking with benzoic acid and purification of the precipitate thus obtained.

STANDARDIZATION OF THE KETOGENIC PRINCIPLE

For the standardization of the ketogenic hormone the rabbit seems to be the best experimental animal, according to Magistris.⁸⁴ This author considers one unit of this principle to be the amount that doubles the total acetone bodies in the blood of a male rabbit two hours after injection. The rabbits used for this test are kept on an oat diet, they should be approximately 2 Kg in weight and they are fasted for five hours before they are used for the test.

Of course other animals may also be used for the standardization of the ketogenic factor. Boenheim and Heimann,⁸¹ for instance use the rat; we use the rat in our laboratory and find it most satisfactory.

EFFECT OF THE KETOGENIC HORMONE ON THE KETONE BODY CONTENT OF THE BLOOD AND URINE

The ketone bodies in the blood, and particularly beta-oxybutyric acid, are greatly increased in the rat after the administration of ketogenic factor, according to Hoffmann and Anselmino⁷⁸ and Magistris,⁸⁴ these observations have been confirmed by Boenheim and Heimann.⁸¹

and by Munoz⁸⁵ and Bix.⁸⁶ and, as already mentioned this hormone also leads to increased excretion of acetone bodies in the rat, according to the pioneer experiments of Burn and Ling.⁷⁷ In the rabbit similar increases in ketonemia have been observed by Magistris.⁸⁷ In the dog, Houssay⁸⁸ obtained ketonuria with a pituitary extract which, however, was very rich in blood sugar raising hormone.

THEORY OF ACTION OF THE KETOGENIC HORMONE

The ketogenic factor is active in thyroidectomized rats and therefore cannot be identical with the anterior pituitary thyrotropic hormone, according to Funk.^{83a} It is also most likely that the hormone is not identical with the blood sugar raising factor, since the former decreases the lipid content of the blood, according to Magistris,^{82b} while the latter has the opposite effect. Chronic administration of the ketogenic hormone decreases the blood sugar in the rat, according to Magistris.⁷⁹ Furthermore, this principle increases the glycogen content of the liver, and this effect is particularly marked if it is given together with thyroid hormone (Magistris^{82b}). This author gave thyroid hormone to rats together with the ketogenic factor and found that under these conditions thyroid administration is unable to deplete the glycogen content of the liver. Chianca⁸⁹ showed that subcutaneous administration of an anterior pituitary extract leads to marked increase in the glycogen content of the liver in rabbits (up to 12.49 per cent), direct injection into the portal vein was still more effective.

These experiments concerning the effect of the hormone on liver glycogen give further support to the theory of its nonidentity with the thyrotropic substance. Additional evidence in this direction is the fact that unlike the other, the ketogenic factor depresses basal metabolism of the rat, according to Hoffmann and Anselmino,⁷⁸ a finding that has since been confirmed by Magistris.⁸⁴

The ketogenic principle increases the specific dynamic action of proteins in the rat, according to Hoffmann and Anselmino⁷⁸ and to Magistris.^{82c}

Raab⁹⁰ and Raab and Kerschbaum⁹¹ have reported numerous experiments on an anterior pituitary fraction which increases the blood lipids and which, according to these authors, is not identical with the ketogenic fraction or any other known pituitary hormone. The name "lipotrin" has been suggested by Raab for this substance.

It is doubtful at the present time whether the ketogenic hormone has any marked influence on the deposition of fat tissue in the organism, but I should like to call attention in this connection to an observation of H. M. Evans and his collaborators,^{90b} who noted the development of marked adiposity in one of their dogs chronically treated with an anterior lobe extract.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY OF THE AMERICAN MEDICAL ASSOCIATION HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A. CARTER Secretary

SPARKLET POCKET CO. SNOW OUTFIT ACCEPTABLE

This outfit is manufactured by Sparklets Ltd, London England. According to the manufacturer, the apparatus is a device for the easy and quick production of a pencil of solid carbon dioxide, suitable for the treatment of certain lesions of the skin. The apparatus consists of several parts. There is a tubular metallic handle or holder (6¼ inches long, six-eighths inch in diameter), into which is placed a small tank or drum of liquid carbon dioxide. This drum is of heavy metal and appears to be of sufficient strength for its purpose, it has a narrow neck, the lumen of which is closed with softer metal that can be punctured with a special needle. A well constructed metal cap screws on and securely closes the holder and drum. The cap contains a needle, which punctures the drum when the cap is screwed home. It also contains a washer, both needle and washer can be easily removed and replaced when they wear out. An expansion chamber screws on to the cap. This consists of a metal cylinder 1½ inches in length and 1 inch in diameter. It is lined with a fine mesh metal screen. Between the screen and the wall of the expansion chamber is a layer of soft material, such as chamois. Four small holes in the wall of the chamber provide the necessary supply of air, ventilation, and variation in expansion, pressure, and so on. The distal end of the chamber consists of an ebonite cylinder (mold) about 1½ inches in length. The diameter of the lumen is six-eighths inch. The distal end is covered with an ebonite rammer, which fits the mold and is used to compress the solid carbon dioxide into a firm pencil or stick.

All parts of the apparatus are well constructed. The carrying case, however, is of pasteboard. It is about 7 inches in length 4 inches in width and 2 inches in depth. The device weighs about 1 pound. The drums are supplied in a set of six in a pasteboard carrying case, 4 by 2½ by 6½ inches. The drums can be refilled and resealed.

It is not an exaggeration to call the device a pocket outfit. The pencil of solid carbon dioxide can be obtained in a minute or two. It is manufactured in the following manner:

A drum is placed in the holder, with the neck of the drum at the distal end of the holder. The cap and expansion chamber are screwed firmly home while the holder is in a vertical position. The needle in the cap punctures the drum, and the carbon dioxide passes through the needle into the expansion chamber, where solid carbon dioxide is formed. The expansion chamber is removed, and the rammer is used to force all the solid carbon dioxide into the mold, where one makes it compact by placing the distal end of the mold on a table and forcing the rammer down with the palm of the hand. Finally, the cap is removed from the mold and the pencil of snow forced out with the rammer.

The pencil of "snow" is about 1½ inches in length and about one fourth inch in diameter. It is sufficiently firm for shaping with a knife (the manufacturer has recently designed a mold to produce the snow stick with a natural point, so that recourse to a knife would be necessary only when the natural point on the snow pencil had become worn down with use) and for the treatment of a number of cutaneous conditions. It is not as hard as commercial "dry ice," which at times is a disadvantage. This lack of firmness causes it to lose its shape rapidly when a comparatively long application or heavy pressure is required. The diameter of the pencil is satisfactory for many conditions. At times it is advantageous to have a pencil of greater diameter. Commercial dry ice has the following advantages. It is firmer and less expensive, and it can be cut into pencils of any size and shape. The disadvan-

tages of dry ice are that one must go to the nearest confectioner or other depot every time the method is to be used. In some, or possibly many, geographic locations, commercial dry ice is not obtainable. The pocket outfit, on the other hand, is always ready for use.

This unit was examined in a clinic acceptable to the Council and was found to give reliable and satisfactory service. The Sparklets Pocket CO Snow Outfit, therefore, is included in the Council's list of accepted devices.

Council on Pharmacy and Chemistry

NEW AND NONOFFICIAL REMEDIES

THE FOLLOWING ADDITIONAL ARTICLES HAVE BEEN ACCEPTED AS CONFORMING TO THE RULES OF THE COUNCIL ON PHARMACY AND CHEMISTRY OF THE AMERICAN MEDICAL ASSOCIATION FOR ADMISSION TO NEW AND NONOFFICIAL REMEDIES. A COPY OF THE RULES ON WHICH THE COUNCIL BASES ITS ACTION WILL BE SENT ON APPLICATION.

PAUL NICHOLAS LEECH Secretary

ORTAL SODIUM (See THE JOURNAL, March 24, 1934, p 928)

The following dosage form has been accepted

Kapskals Ortol Sodium with Amidopyrine Each kapskal (hermetically sealed capsule) contains orl sodium 1½ grains (0.1 Gm) and amido pyrine 1½ grains (0.1 Gm)

SILVOL (See New and Nonofficial Remedies, 1934 p 412)

The following dosage form has been accepted

Capsules Silvol 6 grains

ALYPIN (See New and Nonofficial Remedies, 1934, p 49)

The following dosage form has been accepted

Tablets Alypin ½ grain

TUTOCAIN (See New and Nonofficial Remedies, 1934 p 62)

The following dosage form has been accepted

Amphules 1% Isotonic Solution Tutocain with Supracium 1 20 000 3 cc

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORTS
PAUL NICHOLAS LEECH Secretary

AUTOLYZED LIVER PREPARATIONS

In this issue of THE JOURNAL appears an article by Drs Castle and Strauss¹ in which evidence is presented to show (1) that autolysis of liver does not enhance the potency of liver in bringing about a remission in pernicious anemia and (2) that Autolyzed Liver Concentrate-Squibb as advertised and labeled is not of the claimed potency.

The acceptance of this product by the Council was based on the work of Herron and McElroy.² The Council cannot take exception to the criticism of the report of these authors by Drs Castle and Strauss. Through the courtesy and with the permission of Drs Castle and Strauss their paper was submitted by the Council to E. R. Squibb & Sons for comment. In reply the firm submitted twenty protocols of cases treated with its product.

In accepting liver preparations for the treatment of pernicious anemia, the Council has used as criteria of potency the reticulo-cyte response in uncomplicated untreated cases during the first ten days of administration of the material, and the clinical improvement and restoration of the number of red blood cells and hemoglobin to normal or nearly normal limits within at least two months. In the labeling of products a statement of the antanemic potency in equivalent amounts of fresh liver has been required. The material submitted by the firm in support of the potency claims for its product consisted in

¹ Castle, W. B. and Strauss, M. B. Effect of Autolysis on Potency of Liver in Treatment of Pernicious Anemia this issue p 798

² Herron, W. F. and McElroy, W. S. The Use of Autolyzed Liver in the Treatment of Pernicious Anemia J. A. M. A. 100 1084 (April 8) 1913

reports of cases in which the maintenance efficiency of Autolyzed Liver Concentrate in doses of from one to six teaspoonfuls daily was compared with that of a parenterally administered extract and with those of other preparations for oral use. The evidence seems to demonstrate an efficiency of the Squibb product quite comparable to that of the other preparations employed. However, the data are not of a character that permits estimating the potency on a quantitative basis. Several reports are offered in which hemoglobin and red blood cell counts were made at irregular intervals during administration of the product in doses varying between one and eight teaspoonfuls daily; these indicate definite potency, but the data are not adequate to determine the comparative anti-anemic activity of the preparation. Three case reports are offered in which the reticulocyte counts hemoglobin estimation and red blood cell counts are given during the initial period of administration of the liver concentrate. In only one of the cases are these facts supplied for daily intervals. So far as can be determined the reticulocyte response was submaximal, although the data are not complete. In one patient with an initial red blood cell count of 0.64 million (daily reticulocyte counts are given in this case) 60 Gm of Autolyzed Liver Concentrate was administered daily during the first thirteen days of treatment. The highest reticulocyte count that occurred (on the eighth day) was 33 per cent. A preparation of satisfactory potency would be expected to give on the average a peak rise in reticulocyte count in the neighborhood of 50 per cent. The recommended dosage for the Squibb product is from four to six or more ("or more" gives wide latitude) level teaspoonfuls daily for the first ten days and from one to two level teaspoonfuls daily thereafter. A level teaspoonful of Autolyzed Liver Concentrate weighed in the laboratory of the Council's referee³ averaged about 3 Gm. The patient then received twenty level teaspoonfuls of the Concentrate which would represent the material derived according to the firm's claims (1 Gm is derived from 7 Gm of fresh liver) from 420 Gm of fresh liver, an amount comparable to that from which the Cohn fraction G might be expected to give as good or even a maximal reticulocyte response.

The Council has experienced considerable difficulty in the consideration of the liver preparations that stand accepted for New and Nonofficial Remedies particularly in the matter of labeling so as to indicate comparative potency. Some of the discrepancies in the statements of potency of various preparations have been pointed out in a recently published paper by Drs Dameshek and Castle.⁴

During the past year the Council's referee has been engaged in a revision of standards of assay and methods of labeling antianemic liver preparations. This revision is being considered by the Council. Consequently, in the near future, all firms with products now in New and Nonofficial Remedies will be requested to submit new protocols demonstrating potency according to new standards together with new labels and advertising literature to show that the preparations are properly described.

While this report deals mainly with Autolyzed Liver Concentrate-Squibb, it is not the purpose of the Council to single this out alone as it is quite likely that there may be other preparations the potencies of which are not clearly stated.

In view of the fact that all antianemic liver products in New and Nonofficial Remedies will shortly be reviewed by the

Council with reference to the new standards the Council has decided to postpone further action on Autolyzed Liver Concentrate pending the submission of new evidence by all the manufacturers which will indicate with much greater accuracy than is now possible the comparative potency of all the products. In consideration of the Council's decision, E. R. Squibb & Sons commendably agreed to withhold active promotion of Autolyzed Liver Concentrate.

PERTUSSIS VACCINE, IMMUNIZING (SAUER) (P. D. & CO.)

The Council has already published a report on pertussis vaccine prepared after the method of Dr. Louis W. Sauer and marketed by Eli Lilly & Co. (*THE JOURNAL*, March 3 1934 p. 692). In this report it was stated that the Council does not feel justified at this time in recognizing the use of Pertussis Vaccine of any sort for therapy or prophylaxis until more convincing evidence becomes available. The Council therefore postponed consideration of the Lilly product to await the development of further evidence. Recently Parke, Davis & Co. presented an identical preparation for consideration of the Council. In accordance with its previous decision, the Council voted to consider this preparation as having the same status as that manufactured by Eli Lilly & Co. and postponed consideration to await the evidence to determine its value.

Committee on Foods

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMULGATION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION.

Royal Crest Milk, Inc. Denver
Stearns Dairy Company Denver
Sterling Milk, Inc., Erie Pa.
Sunbury Milk Products Co. Sunbury Pa. (Engles)
Wehr Dairy, Inc., Hamilton Ohio

Description—Bottled pasteurized milk fortified with vitamin D (vitamin D concentrate prepared from cod liver oil) contains 400 U. S. P. X (Revised 1934) vitamin D units per quart.

Preparation—The milk complies with legal requirements and is pasteurized by the standard holding method. See *THE JOURNAL*, July 1 1933 page 34 for description of fortification with vitamin D.

3 The Pharmacopoeia defines a teaspoonful as

1 teaspoonful—4 cc.—1 fluidrachm (approx. 60 grains by weight).

Teaspoons vary a great deal. Frequently coffee spoons are considered teaspoons. In the A. M. A. Chemical Laboratory three different individuals (A, B and C), using 1, 5 and 6 of a group of spoons obtained the following weights as representing a teaspoonful of Autolyzed Liver Concentrate (Lot No. 16675) purchased on the open market.

A. (a) 7.75 Gm. (previous weighings by another individual with the same spoon but on a different lot of powder averaged about 5 Gm.)

B. (a) 2.8 Gm. (b) 3.2 Gm. (c) 3.6 Gm. (d) 3.4 Gm.

(e) 2.9 Gm.

C. (a) 3.2 Gm. (b) 3.5 Gm. (c) 3.6 Gm. (d) 3.6 Gm.

(e) 3.5 Gm. (f) 2.6 Gm.

The Pharmacopoeia defines a teaspoonful as 4 cc. Four cc. volume of Autolyzed Liver Concentrate Powder was found to weigh 1.8 Gm. It is understood that E. R. Squibb & Sons considers 3.6 Gm. as a teaspoonful. It seems that the referee's figure is less than the average weight but the benefit of this calculation redounds to E. R. Squibb & Sons.

⁴ Dameshek, William and Castle, W. B. Assay of Commercial Extracts of Liver for Parenteral Use. *J. A. M. A.* 103: 802 (Sept. 15) 1934.

Vitamins—The vitamin D concentrate used and the fortified milk are regularly tested biologically. Clinical investigation shows this milk to be a reliable antirachitic agent if the proper amount is used.

Claims of Distributors—A vitamin D fortified antirachitic pasteurized milk having otherwise the flavor and food values of usual pasteurized milk.

- (a) MASTER WHITE BREAD (SLICED)
(b) MASTER BREAD SLICED (TWINS)
(c) THIN MASTER BREAD SLICED

Manufacturer—Zinsmaster Baking Company, Minneapolis

Description—(a) and (b) Sliced white breads made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p 817), prepared from patent flour, water, sucrose, shortening, powdered skim milk, sodium chloride, yeast, a bleaching agent consisting of corn and soya bean flours, and a yeast food containing calcium acid phosphate, ammonium sulphate, sodium chloride, potassium bromate, potassium iodate and corn starch.

(c) Sliced white bread made by the sponge dough method (method described in THE JOURNAL, March 5, 1932, p 817) prepared from patent flour, water, sweetened condensed whole milk, sucrose, shortening, sodium chloride, yeast, a bleaching agent consisting of corn and soya bean flours and a yeast food containing calcium acid phosphate, ammonium sulphate, sodium chloride, potassium bromate, potassium iodate and corn starch.

DORSEL'S SEAL OF KENTUCKY HIGH GRADE FLOUR, BLEACHED, PHOSPHATE ADDED

Manufacturer—The Dorsel Company, Inc. Newport Ky.

Description—Patent flour blended from hard and soft winter wheat with added calcium acid phosphate, bleached.

Manufacture—Selected wheat is cleaned, scoured, tempered and milled by essentially the same procedures as described in THE JOURNAL, June 18, 1932, page 2210. Chosen streams of bleached flour are blended, two thirds hard winter wheat flour being used to one third soft winter wheat flour, three-fifths ounce Novadex (benzoyl peroxide and calcium phosphate) and three fifths pound calcium acid phosphate are added per barrel of flour.

WARRANTY SIEVED CELERY

Manufacturer—The Nielsen Corporation, Ltd. Oakland, Calif.

Description—Sieved celery prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacture—Matured celery is delivered to the plant and immediately washed. The hearts and inner stalks, free of leaves are processed and canned by essentially the same procedure as described for Warranty Sieved Spinach (THE JOURNAL, Feb 2, 1935, p 399).

Analysis (submitted by manufacturer) —	per cent

WARRANTY SIEVED APRICOTS

Manufacturer—The Nielsen Corporation, Ltd. Oakland, Calif.

Description—Sieved apricots prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacture—Fully ripe apricots are pitted by hand, thoroughly washed, sorted, sieved and subsequently processed and canned as described for Warranty Sieved Spinach (THE JOURNAL, Feb 2 1935, p 399). If not immediately sieved the apricots are heated in an atmosphere of steam, canned hot, and used later as needed for sieving.

Analysis (submitted by manufacturer) —	per cent
Moisture	85.7
Total solids	14.3
Ash	0.5

Claims of Manufacturer—Specially intended for infants, children and convalescents and for special smooth diets. Only warming is required for serving.

EVANGELINE EVAPORATED MILK UNSWEETENED, STERILIZED

Manufacturer—Evangeline Milk Co. Sawyer, Wis.

Description—Unsweetened, sterilized, evaporated milk.

Manufacture—The procedure of evaporation and canning, and the analysis are essentially the same as for the usual evaporated milk (THE JOURNAL, April 16, 1932 p 1376).

Claims of Manufacturer—See announcement on the advertising of the Evaporated Milk Association (THE JOURNAL, Dec 19, 1931, p 1890).

"WHAT'S IN A CAN OF FRUITS ? VEGE-TABLES ? FISH ? PROMOTIONAL ADVERTISING

Sponsor—Department of Home Economics, American Can Company, New York.

This department distributes information on various canned foods.

Advertising—The booklet discusses the varieties, grades and nutritive values of various canned fruits, vegetables and fish.

SATURDAY MARCH 9 1935

THE SURGICAL TREATMENT OF GALLSTONE DISEASE

The causes of gallstone formation are believed to be infection of the gallbladder stasis of the bile in the gallbladder and certain metabolic alterations, notably those of cholesterol. The infection may be ascending, from the intestine into the extrahepatic bile tracts or hematogenous, by way of the liver which acts as a bacterial filter. Undue relaxation of the sphincter of Oddi, resulting from disturbed motor function of the extrahepatic bile tracts brought about by a vegetative nervous imbalance, may serve to facilitate the invasion of the tracts by the intestinal flora.

Infection of the gallbladder with the accompanying bile stasis impairs the digestion of fats. A far graver consequence, however, is the damage to the liver cells undoubtedly present in a greater or lesser degree in every case of gallbladder infection. This leads to a disturbance of one of the most important liver functions, namely, the regulation of the carbohydrate metabolism. The prevention and treatment of damage to liver cells becomes therefore the most important problem in the therapy of gallstone disease. The measures recommended have in mind the sparing of liver function as far as possible by a proper dietetic regimen and a storing up of glycogen. Administration of small doses of insulin covered by a proper amount of dextrose seems to be helpful in stimulating the glycogen storing faculty of a damaged liver.

Jaundice is an important problem for the surgeon, because of the tendency to the much feared cholemic bleeding. It should be noted that the term "cholemic" is a misnomer. The tendency to protracted bleeding in a jaundiced patient, it has been shown conclusively, is not due to the presence of bile components in the blood but to liver damage. Wildegans implanted the common duct of a dog into the vena cava and failed to find any tendency to increased bleeding. The blood calcium content of jaundiced patients is as a rule normal and the entire concept of retarded blood coagulability and lowered blood calcium is no longer tenable. More

recent researches point, in fact, to an increase in the antiprothrombin as the cause of tendency to bleeding. The failure to secrete and maintain the proper antiprothrombin blood content is the result of damaged liver function. Of the many measures for combating this dangerous complication, blood transfusion administered on the day before the operation and after the operation is most effective.

The focusing of the attention on the liver damage has resulted in a more prolonged and more thorough preoperative treatment, with a lowering of mortality. With regard to the choice of the operation, it may be said that the simpler the intervention the lower the mortality. A cholecystectomy without opening into the common duct gives a low mortality. The statistics of the Mayo clinic show a mortality of 19 per cent in 23,796 cholecystectomies. The same clinic, however, reports a mortality of 72 per cent in 3,246 cholecystectomies with drainage of the common bile duct. The mortality is highest from operations done in the course of an acute attack and lowest when carried out in the chronic stage. Internists as well as surgeons are now agreed as to the advisability of an early operation before the development of advanced pathologic conditions of the bile tracts, the liver, the pancreas and the vital organs. The recurrence of symptoms after the removal of the gallbladder has been much discussed. The dictum that recurrent colicky attacks are invariably due to an overlooked stone is no longer accepted generally. Formation of new stones in the liver in the absence of the gallbladder, while rare, has been known exceptionally to take place. Colicky attacks, however, can occur in the absence of stones. Moreover, the occurrence of true colicky attacks is rather infrequent.

The more common recurrent complaints are epigastric fulness, belching, transient diarrheas, occasional icterus with mild fever, loss of weight, nervousness and fatigue. Adhesions, chronic pancreatitis, persistent cholangitis and hepatitis have all been considered as possible causes. Surgeons with extensive experience in this field have been impressed with disproportion in the pathologic conditions found at reoperation and the existing symptoms. Subjective symptoms may be entirely wanting in the presence of extensive pathologic changes, and the reverse, severe symptoms, may be complained of in the presence of insignificant pathologic alterations. This gave rise to the dyskinetic theory (Bergmann) of disturbance of the extrahepatic bile tracts and the sphincter of Oddi, an upset in the functioning of the vegetative nervous system. It appeared indeed that the psychic constitution and the state of the vegetative nervous system played a more important part in the occurrence of recurrent complaints than the existence of gross pathologic lesions.

Internal medical treatment is quite successful in relieving the recurring complaints in a high proportion of the cases. The treatment consists of a proper dietetic regimen and the exhibition of drugs that disinfect

the bile tract, of cholagogue drugs and of duodenal drainage

As for the operation of choice, there appears to be now much more unanimity in favor of cholecystectomy than there was a decade ago. Although one still hears individual voices favoring cholecystotomy, the latter is being reserved more and more for the severe cases of cholangitis, for deep jaundice, for liver atrophy and for elderly patients in a much reduced general state.

With the indications for the exploration of the common bile duct rather clearly established, the question of whether or not to drain the duct is still open to debate. The views oscillate between Kehr's dictum made in 1913 that the duct be drained in every instance of its being opened, and Deaver's pithy query "Why drain a drain?" The disadvantages of a drain in the duct are the possibility of development of stenosis of the duct with its tragic consequences, and the loss of fluids and bile to the organism from draining the bile away from the intestine. It has been recognized but recently that a loss of from 500 to 1,500 cc. of bile daily is a serious matter for a run-down patient. The advantages of drainage of the duct especially for the toxic cases, is the more rapid detoxification of the liver and the bile tracts and sparing the bowel the introduction of the infected bile. The tendency is to suture the duct and to place a drain down to the suture line rather than to drain the duct itself. The enthusiasm of certain European surgeons for anastomoses between the common bile duct and the duodenum (Finsterer) is not shared by American surgeons, because of the demonstrations of the ever present possibility of an ascending infection.

INTERMEDIARY METABOLISM OF FAT

The study of the processes of intermediary metabolism *in vivo* presents many experimental difficulties to the investigator. The body secretions and excretions available for analytic purposes, namely, blood, digestive juices, urine, spinal fluid, milk and feces give a fairly accurate reflection of the picture of the chemical situation within the body. Certain of the fluids, the urine, for example, present merely the terminal metabolic products for study. These materials aid in writing only the final chapters in the story of intermediary metabolism. The events leading to these conclusions are generally obtained by inference. Investigators have long sought experimental conditions *in vivo* which, by virtue of the presence of a limited number of variables, would aid in the elucidation of the chemical reactions occurring in metabolism. A partial attainment of this objective is made available through the natural spawning habits of the salmon. During its long migration to the spawning waters, this fish does not partake of food; at least the alimentary tract is never found to contain food detritus, and the digestive fluids are practically inactive. The migratory period represents therefore,

a time during which all the products formed in the organism must arise from endogenous sources, the extraneous variable of ingested food has been excluded. This fact makes the salmon peculiarly suitable for studies of the mobilization of body materials and their transformations. The discovery of nucleic acid in the spermatozoon heads of the Rhine salmon carried with it the proof that nucleic acid need not be formed from purine precursors of the diet. The great increase in the nucleoprotein-rich generative organs during the migration up the Rhine occurs concomitant with a decrease in muscle tissue. This must mean, therefore, that nucleic acid is formed directly or indirectly from muscle protein.¹

The spawning habits of the Atlantic salmon make this fish well adaptable for studies of the mobilization of depot fat. The journey from the sea up the rivers to the spawning grounds, with a cessation in feeding demands the expenditure of much energy, which has to be supplied mainly by reserve fat. Furthermore, considerable amounts of fat accumulate in the gonads, and this material must be transferred from fat depots or synthesized from nonlipid precursors. The fish after spawning contain as little as 0.3 per cent of fat in the muscles, contrasted with from 13 to 14 per cent present in a fish fresh from the sea. The recent study of Lovern² has been designed to investigate the chemical changes involved in this fat mobilization. By selecting salmon of different degrees of emaciation it has been possible to obtain samples of depot fat from fish in which the percentages of reserve fat form a rapidly decreasing series. A detailed analysis of the fatty acids of these specimens was made in order to determine whether fat mobilization is a selective process. For example, if certain acids such as the more unsaturated ones, or glycerides of these acids are mobilized more readily than the saturated components, the fats from the more emaciated fish should show an increasing accumulation of saturated constituents.

The data obtained show a rather surprising, almost nonselective, mobilization of the depot fat. The smaller amount of fat present in emaciated salmon had a fatty acid composition quite similar to that of samples obtained from fish in a better state of nutrition. The composition of the ovarian fat, however, was quite different from that of the depot fat in the same animal from which it was probably derived, being characterized by a higher degree of unsaturation. As this selective formation of ovarian fat could not be correlated with a chemical change in the remaining body fat it appears that fat is mobilized in the first instance almost nonselectively. A portion of this mobilized depot fat must then be selectively removed by some organ and passed on to the ova, the remainder being consumed as fuel. The specific transfer of highly unsaturated con-

1 Jones, Walter. *Nucleic Acids: Their Chemical Composition and Physiological Function*. 2 London: Longmans Green & Co. 1920.
2 Lovern, J. A. *Biochem. J.* 28: 1955 (No. 6) 1934.

stituents to the ovaries has a possible suggestive parallel in the selective acquisition by the phospholipids of certain animals of the most unsaturated of the available fatty acids.³ Further studies of the other types of lipids deposited in the ova under these conditions should amplify knowledge of the physiologic role of the phospholipids and their constituent fatty acids at the same time adding a few touches to the incomplete picture of the intermediary metabolism of the lipids

Current Comment

PHYSICIANS AND THE OPTICAL RETAIL CODE

Demands are being made by the Optical Retail Trade Code Authority, in a letter addressed "To Oculists and Physicians Dispensing Ophthalmic Products," that the physician to whom it is addressed fill out a questionnaire relative to the nature and extent of the physician's optical business and pay assessments amounting to \$3 for each employee in his service. It is asserted that "physicians selling glasses or servicing prescriptions" come fully within the scope of the Optical Retail Code. The assessment is for the support of the Optical Retail Trade Code Authority, a trade organization. The Optical Retail Trade Code Authority, by which these demands have been made, is organized under the National Industrial Recovery Act. The National Industrial Recovery Act does not purport in any way to regulate or control the practice of medicine. It specifically relates to "industry" and "trade" and to industrial and trade associations or groups. It relates only to transactions in or affecting interstate or foreign commerce. Under no provision of the act can a physician who confines his work to rendering professional medical services be subjected to any provision of the code or to any assessment under the code. A person who on his own account commercially buys and sells eyeglasses and spectacles and makes a commercial profit on the transaction is presumably within the purview of the Optical Retail Trade Code, even though he happens to be a physician. A physician, however, who buys and sells eyeglasses and spectacles only as the agent of patients for whom he prescribes them and without making any commercial profit on the transaction is not within the terms of that code. The fact that a physician charges for his professional services in prescribing and fitting glasses and spectacles does not alter the situation. The American Medical Association has protested against the attempt of the Optical Retail Trade Code Authority to bring physicians as such within the scope of the code that it administers. Pending the adjustment of those protests, physicians who are engaged in strictly professional work are advised to refrain from answering the questionnaire sent them by the Optical Retail Trade Code Authority and to refrain from paying the attempted assessment for the support of that code authority. The outcome of the protest will be promptly reported in *THE JOURNAL*.

NOBEL PRIZE LECTURES ON ANEMIA

When the Nobel Prize in Medicine was awarded to Drs. Whipple and Minot jointly, it was universally considered a fitting tribute to years of painstaking and productive effort. The tone of their lectures,¹ given before the Caroline Institute at Stockholm, is one of sober review and incomplete accomplishment. Profound study of a subject often produces an acute sense of incompleteness that is absent from the point of view of the dilettante. This sense is amply demonstrated in the words of both distinguished investigators. Thus, Minot says, "the physician, however, must do more for his patient than prescribe a proper amount of liver, stomach, or the like, he should attend to all aspects of the case and not neglect attention to the individual's manifold problems of thought and action." And Whipple's closing paragraph in the current issue of *THE JOURNAL* furnishes similar evidence of what is probably the most notable characteristic of the close student of disease. Emulation of the accomplishments set forth in these and other papers is impossible for most, but appreciation of remaining problems is a state of mind that can be widely understood.

AMEBAS ON THE HANDS

Accurate information concerning the presence and survival of *Endamoeba histolytica* on the hands of infected persons is significant for the control of amebic infestation. Spector¹ and her collaborators have now reported work designed to determine the presence of amebic cysts on the hands under natural conditions. When a carrier was detected in routine examination, a second examination was requested. At this examination the patient was asked to pass a fresh stool. Immediately after using the toilet paper and before washing the hands, the subject was instructed to rinse the hands thoroughly in sterile saline solution or distilled water in a sterile vessel. The finger nails were then thoroughly cleansed with a sterile tooth pick and cut with sterile scissors into the same container. These washings and parings were placed in large sterile centrifuge tubes and centrifuged at a medium speed for from five to ten minutes. The supernatant fluid was removed and the sediment examined with 1:1,000 aqueous eosin and an iodine solution (5 per cent aqueous potassium iodide saturated with iodine and diluted with equal parts of distilled water) for the ready detection of cysts and for the determination of their state as to viability. Endo plates were also made from the washings in fifty-four cases in order to determine the relative persistence of members of the coli-aerogenes group of bacteria. Of the seventy-four persons thus examined, the washings of five (6.8 per cent) were positive; two showed a few live cysts of the large variety, one showed a few dead cysts of the large variety, and two showed live cysts of the small variety. In the fifty-four that were cultured on Endo's medium, fifteen (27.7 per cent) were positive.

2 Spector, Bertha Kaplan, Foster, J. W. and Glover, N. C. *Endamoeba histolytica* in Washings from the Hands and Finger Nails of Infected Persons. *Pub. Health Rep.* 50: 163 (Feb. 8) 1935.

for organisms of the coli-aerogenes group. It appears from these data that persons whose stools are known to contain living *Endamoeba histolytica* organisms do not frequently contaminate their hands with these organisms under ordinary conditions. It therefore seems that contamination of food by carriers of *Endamoeba histolytica* under the ordinary conditions of food handling occurs, if at all, infrequently.

Association News

MEDICAL BROADCASTS Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4:30 to 4:45, central standard time. The next three broadcasts will be delivered by Dr. W. W. Bauer. The titles will be as follows:

- March 14 Physical Defects.
- March 21 Rickets
- March 28 This Is No April Fool

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4:15, central standard time. The next three broadcasts will be as follows:

- March 12 Food and Drug Law Revisions Paul N. Leech, Ph.D.
- March 19 White Collar Hazards W. W. Bauer, M.D.
- March 26 Tonics and Sedatives Morris Fishbein, M.D.

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bill Passed—S. 15 has passed the senate and the house proposing to repeal the laws regulating the sale, possession or distribution of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

Bill Introduced—H. 108, to amend the workmen's compensation act, proposes to make the following occupational diseases compensable: anthrax, caisson disease, miners' diseases, including cellulitis, bursitis, ancylostomiasis, tenosynovitis and nystagmus, glanders, compressed air illness, epitheliomatous cancer, cataract in glass workers, dermatitis, and poisoning from arsenic, lead, zinc, mercury, phosphorus, benzene and its homologues, wood alcohol, chrome, radium, formaldehyde and its preparations, dope, bisulphide, methyl chloride, carbon monoxide gas, contact with petroleum products, and from sulphuric, hydrochloric or hydrofluoric acids.

ARKANSAS

Bills Passed—The following bills have passed the senate: S. 332, to authorize the sexual sterilization of habitual criminals whom the bill defines as persons convicted to final judgment three times for felonies, and S. 344 proposing to authorize the sexual sterilization of insane, idiot, imbecile, feeble-minded or epileptic inmates of state institutions. H. 189 has passed the house and the senate, proposing to prohibit the sale of barbituric acid derivatives and/or compounds thereof except on the prescription of a licensed physician.

Bills Introduced—S. 305 proposes to regulate the practice of occupational therapy and to create a state board of examiners of occupational therapists, to be composed of three physicians nominated by the Arkansas State Medical Society, and two trained occupational therapists in governmental service. Occupational therapists are not to practice occupational therapy

except under the direction and prescription of a licensed physician. H. 188 proposes to provide compensation to workmen for injuries arising out of or in the course of their employment. The employer is to be required to furnish medical, surgical and other attendance or treatment, nursing and hospital services and medicines, crutches and apparatus, for such period as the nature of the injury or the process of recovery may require. Apparently the employer is to have the right to designate the physician and the hospital that are to treat or care for the injured employee. If the employer does not provide the services referred to after a request by the employee, the employee may obtain them himself at the employer's expense. H. 373 to amend the osteopathic practice act, proposes (1) to eliminate the provision in the present law which prohibits osteopaths from prescribing or using drugs or from performing major or operative surgery and to provide that an osteopath is authorized to practice osteopathy in all its branches as taught and practiced in legally incorporated schools of osteopathy, and (2) to authorize osteopaths to make and sign birth and death certificates and all other certificates pertaining to public health.

CALIFORNIA

Society News—Dr. Harry G. Huffman addressed the Orange County Medical Society in Santa Ana, January 8, on "Recent Changes in the Practice of Medicine."—At a meeting of the Placer County Medical Society, January 8, Dr. Emile F. Holman, San Francisco, discussed "Treatment of Pyogenic and Tuberculous Pulmonary Suppuration—Clinical and Experimental Observations."—Dr. Steele F. Stewart, Los Angeles, addressed the Ventura County Medical Society, January 8, on "Indications for Surgery of the Sympathetic Nervous System."—Dr. Kellogg Speed, Chicago, addressed the Los Angeles Surgical Society, February 20, on "Treatment of Fractures of the Neck of the Femur."—Dr. Mont R. Reid, Cincinnati, addressed the San Diego Academy of Medicine, March 7, on "Treatment of Peripheral Vascular Diseases."

Bills Introduced—Assembly Constitutional Amendment No. 46 proposes that the California constitution be amended so as to permit the legislature to amend the chiropractic initiative act in the following particulars: (1) to define chiropractic to be "the art and science of locating and adjusting by hand to restore to normal any abnormal anatomic relation for the purpose of removing interference with the transmission of nerve force and also include all natural, drugless, mechanical, hygienic and sanitary measures incident to the care of the body when administered previous to or subsequent to an adjustment." (2) to provide that "one form of license or certificate shall be issued by the board of chiropractic examiners, which shall be designated 'License or certificate to practice chiropractic and also natural, drugless, mechanical, hygienic and sanitary measures incident to the care of the body,' which 'license or certificate shall authorize the holder thereof to practice chiropractic but shall not authorize the practice of medicine, surgery, osteopathy, dentistry, or optometry," and (3) to require chiropractors to register annually on or before January 1 with the board of chiropractic examiners and to pay an annual registration fee of from \$5 to \$10. A. 2309 proposes to create a state board of regulation of hospital associations to license so-called hospital associations to engage in the business of issuing contracts for furnishing medical, hospital, nursing and dental care.

CONNECTICUT

Bills Introduced—S. 101 proposes to authorize the state department of health to investigate the cause and the prevention and treatment of cancer and to take such steps as may be necessary to reduce the mortality due to cancer. S. 455 proposes to forbid hospitals receiving appropriations from the general assembly to refuse to admit for treatment therein patients suffering from venereal diseases. S. 657, to amend the dental practice act, proposes that the provisions of the dental practice act prohibiting a corporation from owning or operating a dental office shall not apply to welfare dispensaries.

Grant for Dental Research—Continuance of a dental research project in Yale University School of Medicine has been made possible through a grant of \$17,500 by the Carnegie Corporation of New York. This program, instituted in July 1929 under a grant of the Rockefeller Foundation, is an intensive study of the teeth in relation to the body in general by physicians, radiologists, bacteriologists, pathologists and dentists (*THE JOURNAL*, June 29, 1929, p. 2176). The original study group included Dr. Milton C. Wintermiz, Dr. Samuel C. Harvey, the late Dr. William A. LaField, Dr. Felix d'Herelle

George H. Smith, Ph.D., Dr. Raymond G. Hussey and William Downs Jr., D.D.S. According to Yale University, the interest of a group of New Haven dentists in the project as a whole has been demonstrated by the formation of the Dental Clinic Society, which provides more than 500 treatments monthly for indigent patients. The society has its own professional staff but is conducted in close cooperation with the dental study group and community social agencies.

DELAWARE

Bills Introduced—S 91 proposes to authorize a divorce if either spouse has been adjudged feeble-minded, epileptic and chronically or recurrently insane and has been confined to an institution for mental diseases for at least five years. H 223 proposes to prohibit physicians, surgeons or registered nurses from testifying concerning any communications entrusted to them in their professional capacity and necessary and proper to enable them to discharge their duties.

DISTRICT OF COLUMBIA

Medical Bills in Congress—S 1016 has passed the Senate proposing to empower the health officer of the District of Columbia to authorize the disinterment and reinterment of bodies in cases in which death has been caused by certain contagious diseases. S 31 has passed the Senate and House, providing for the issuance of a license to practice the healing art in the District of Columbia to Dr. Chester C. Groff. S 2013, introduced by Senator Copeland, New York, proposes to provide for the issuance of a license to practice the healing art in the District of Columbia to Dr. Pak Chue Chan.

Meningitis Quarantine—About 1700 transients were placed under quarantine by health authorities, February 6, because of an outbreak of spinal meningitis, newspapers reported. One death occurred on February 7. About two thirds of the number were released, February 14, but about 300 were still confined because cases had developed in the lodging houses in which they were quartered. All transient lodging houses were quarantined. About 450 men quartered in small hotels under contract were brought back into the lodges, but those living in private homes were not affected by the ban, it was said.

Dr. Wilmer Honored—A homecoming dinner was held in honor of Dr. William H. Wilmer, January 24, by the Augustus P. Gardner Post number 18 of the American Legion. Dr. Wilmer has returned to Washington, following his resignation as director of the Wilmer Institute of Ophthalmology of Johns Hopkins University School of Medicine, Baltimore. He had occupied this position since 1925 when the institute was established, as professor of ophthalmology in the medical school. He had served in a similar capacity at Georgetown University School of Medicine from 1906 to 1925. Members of the Medical Society of the District of Columbia were invited to attend this dinner, which was under the general direction of Dr. Robert U. Patterson, surgeon general of the U. S. Army. Dr. Wilmer is a charter member of post number 18.

FLORIDA

Society News—Dr. George N. MacDonell, Miami, was elected president of the Florida Public Health Association at its meeting in Jacksonville, Dec. 3-5, 1934. Vice presidents elected are Dr. Noble A. Upchurch and Johanna L. Sogaard, Jacksonville, and Stewart G. Thompson, Dr. P. H., Jacksonville, secretary. Dr. Francis Carter Wood, New York, addressed a dinner meeting in Tampa, January 19, on cancer, under the auspices of the Hillsborough County Medical Society. The Dade County Medical Association was addressed in Miami, February 1, by Drs. Don C. Eskew on "Fractures of the Spine," and Max Dobrin, "Gonococcus Aortitis with Aneurysm and Bicuspid Aortic Valve."

GEORGIA

Personal—A giant magnet was recently presented to the University Hospital, Augusta, by the Masonic Fraternity as a memorial to the late Dr. William C. Kellogg, for many years professor of ophthalmology and otolaryngology, University of Georgia Medical Department. Dr. John W. Oden, Grace-wood, has been appointed superintendent of the state hospital at Milledgeville.

Bills Introduced—H 536 proposes to require any physician or surgeon treating a person suffering from gunshot or knife wounds to report such facts to the mayor of the city where such act occurs, or, if the act occurs without the limits of a municipality to the sheriff of the county. H 221 proposes to

authorize the sexual sterilization of inmates of state institutions, who, if released without being sterilized, would likely procreate children with a tendency to serious physical, mental or nervous disease or deficiency. H 275 proposes to create a board of physiotherapy examiners and to regulate the practice of physiotherapy. The practice of physiotherapy is defined as "the diagnosis and treatment of human ailments by the use of any natural force or agency, the basis of which is water, heat, sun light, electricity or electrically produced energies, mechanical appliances, ultraviolet light, infra-red light, manipulations, corrective exercises, dietetics, massage, external applications and mineral baths." The bill proposes to prohibit anybody but a licensee of the board from practicing physiotherapy as defined but exempts (a) persons authorized by the law to practice medicine and surgery and (b) persons who at the time of the enactment of the bill are members of the Georgia State Association of Physical Therapy or who have been engaged in the practice of physiotherapy at least one year prior to the enactment of the bill. An applicant for a license must be a high school graduate or have an equivalent education, must have studied physiotherapy for two years in a school of physiotherapy approved by the board, and must pass a satisfactory examination in history, anatomy, physiology, chemistry, pathology, diagnosis and treatment, bacteriology, massage, therapeutics, clinical physiotherapy and such added subjects as shall subsequently be taught by accredited schools of physiotherapy.

IDAHO

Bill Introduced—H 194 proposes to authorize the department of public welfare to enter into agreements with boards of county commissioners to assist in the necessary hospitalization costs of persons on unemployment relief.

ILLINOIS

Society News—Dr. Harry M. Hedge, Chicago, addressed the Lake County Medical Society at Waukegan, February 12, on "Infections of the Skin."—At a meeting of the Decatur Medical Society, February 19, Dr. Claud R. G. Forrester, Chicago, discussed "Reduction of Fractures Under Local Anesthesia with Ambulatory Treatment."—The DeWitt County Medical Society was addressed, February 25, by Dr. John A. Wolfer, Chicago, on "Problems in the Management of Gall bladder and Biliary Tract Disease."—Speakers before the Warren County Medical Society, February 27, were Drs. George Karl Fenn and Guy M. Cushing, Chicago, on "Angina Pectoris" and "Acute Perforating Gastric and Duodenal Ulcers," respectively. Dr. Charles J. Drueck, Chicago, addressed the Will-Grundy County Medical Society, January 30, on "Anorectal Disease, Its Relation to the General Health."—Dr. Philip H. Kreuscher, Chicago, discussed the subject of backache before the Kane County Medical Society in Aurora, February 13.

Chicago

Course in Tumor Pathology—Dr. Richard H. Jaffe will begin a course in tumor pathology at the Cook County Hospital, March 14. Lectures, which are designed for practicing physicians as well as pathologists, will be given every Thursday for ten weeks.

Society News—At a meeting of the Chicago Society of Allergy, February 18, speakers were Drs. Lloyd F. Catron on "Role of Allergy in Response to Acute Infections," and Elias Sellinger, "Effect of Human Lens Protein on Senile Cataract."—Members of the Kansas City Ophthalmological and Otolaryngological Society were guests of the Chicago Ophthalmological Society at its meeting, February 18, speakers included Drs. Elmer A. Vorisek on "Changes of the Refraction in Children with Convergent Strabismus," George P. Guibor, "Results Obtained by Refractive Correction Alone in Children with Squint," and Paul H. Reed, until recently of River Forest, Ill., and Leo L. Mayer, "Bilateral Temporal Pterygia."—The Chicago Pediatric Society was addressed, February 19, by Drs. Robert E. Cummings on "Massive Collapse of the Lung in Pneumonia," Mandel L. Spivek, "Obstruction of Bronchi Due to Tuberculous Lesions," and Louis W. Sauer, Evanston, Ill., "Enteritis: Its Control and Prevention by the Dick Diet Kitchen and Nursery Technic."—Dr. Walter Freeman, Washington, D. C., among others, addressed the Chicago Neurological Society, February 21, on "Ventriculography with Colloidal Thorium Dioxide as a Contrast Medium."—Drs. Lowell T. Coggeshall and Oswald H. Robertson were among the speakers before the Chicago Society of Internal Medicine, February 25, they presented "Study of Repeated Attacks of Experimental Pneumococcus Lobar Pneumonia in Dogs."

INDIANA

Bill Enacted—H 211 has become a law, authorizing counties, cities and towns to supply insulin free of charge to citizens who are in need of insulin for treatment of diabetes and who are financially unable to purchase the drug. S 139 has become a law, creating a board of beauty culture examiners and regulating the practice of beauty culture, manicuring and electrolysis. Licentiates are to be permitted to remove superfluous hair from the face, shoulders or arms of any person by the use of an electric needle.

Bills Passed—H 365 has passed the house, proposing to authorize the construction and maintenance of hospitals by cities of the fourth and fifth class. Such hospitals are to be open on reasonable terms to all persons and to all physicians who desire to place patients therein. S 185 has passed the senate, proposing to prohibit any private hospital from denying any member of the immediate family of any patient access to the patient's room at any time. No person employed by a private hospital is to change or refuse to administer the treatment prescribed by the patient's physician. The board of health, if this bill should be enacted, is to be authorized to investigate the management, facilities, accommodations and rules of any private hospital that are alleged to be discriminatory and any other practice which, in the judgment of the board, is not conducive to the comfort, convenience or necessary privacy of patients. After a hearing, the board may make such orders as it deems necessary to correct the conditions complained of. If such a hospital shall refuse to carry out the orders of the board, the secretary of state is to revoke the authority of the hospital to transact business.

Bills Introduced—H 387 proposes to accord hospitals and physicians, treating persons injured through the negligence of others, liens on all rights of action, claims, judgments, settlements or compromises accruing to the injured persons by reason of their injuries. The bill also proposes to repeal the law enacted on March 9, 1933, according hospitals liens under the circumstances stated. H 459, to amend the chiropody practice act, proposes that any person over 21 of good moral character, who desires to engage in the correction of defective feet without the use of surgical instruments, appliances or equipment of any kind and without the use of drugs, chemicals or medicines, shall on the payment of \$25 be entitled to a license without examination and without showing any educational qualifications whatever. H 487 proposes, as a condition precedent to the issuance of a license to wed, that both parties to a proposed marriage present certificates from licensed physicians that they are free from any transmissible disease. H 490 proposes on the commitment of a person to an institution for the insane that he or she be rendered sterile.

IOWA

Society News—Speakers before the Page County Medical Society in Shenandoah, Dec. 5, 1934, were Drs A. Fred Watts, on "Principles of Infant Feeding," Carl E. Sampson, "Diagnosis of Acute Mastoiditis," and John C. Parsons, "Creston Neutrophilic Lobe Counts."—Dr. Abraham F. Lash, Chicago, addressed the Scott County Medical Society, Dec. 4, 1934, on "Puerperal Sepsis."—Dr. Emil Novak, Baltimore, will address the Linn County Medical Society, Cedar Rapids, March 13, on "Functional Disorders of Menstruation." He will address the Polk County Medical Society, Des Moines, March 14, on "Endocrine Aspects of Sterility."—Dr. Henry W. F. Woltman, Rochester, Minn., addressed the Des Moines Academy of Medicine and Polk County Medical Society, February 12, on "Deficiency Diseases of the Nervous System."—Dr. Donald J. Wilson, Omaha, discussed the "Diagnosis and Treatment of Oral Lesions" before the Black Hawk County Medical Society, January 15, in Waterloo.

Bills Introduced—H 174, to amend the osteopathic practice act, proposes (1) to remove the provision in the present law which specifically denies osteopathic physicians and osteopathic physicians and surgeons the right to prescribe or give internal curative medicines, (2) to permit osteopathic physicians to practice obstetrics and minor surgery, and (3) to define osteopathic practice as "that method of rehabilitating restoring and maintaining body functions by and through manual stimulation or inhibition of nerve mechanism controlling such body functions, or by the correction of anatomical maladjustment and/or by other therapeutic agents, methods and modalities used supplementarily thereto but such supplementary agents, methods or modalities shall be used only preliminary to, preparatory to and/or in conjunction with such manual treatment" and to declare that such osteopathic practice is not the practice of medicine within the meaning of the medical practice act.

H 237, to amend the chiropractic practice act, proposes (1) to define chiropractors as "persons who treat human ailments by the adjustment by hand of the articulations of the spine or by other incidental adjustments calculated to remove any cause and/or effect of any nerve interference, and who may use, in connection therewith, physical, mechanical, hygienic and sanitary measures" and (2) to provide that a license to practice chiropractic shall not authorize the holder thereof to practice operative surgery, osteopathy, nor to administer or prescribe any drug or medicine included in materia medica.

KANSAS

Bills Introduced—S 359 and H 464 propose to authorize the establishment of community hospitals in counties having a population of more than 43,000 and less than 55,000. The bills propose that, in the management of such hospitals, no discrimination shall be made against practitioners of any school of the healing art recognized by the laws of the state and that all legal practitioners shall have equal privileges in treating patients therein. The patients are to be granted the absolute right to employ at their own expense their own physicians and such physicians are to have exclusive charge of the care and treatment of their patients. H 502 authorizes two or more counties to establish jointly district hospitals and homes for the care and maintenance of the poor.

MASSACHUSETTS

Personal—Dr. William P. Murphy, Boston, was awarded the Order of the White Rose by the president of Finland with a rating of commander of the first rank, in December 1934. He was also made a member in December of the Kaiserliche Leopoldinische-Carolingische Deutsche Akademie der Naturforscher, which was established in 1652.—Dr. George W. Gale observed his ninety-eighth birthday in Saugus, February 3. Dr. Gale is a former chairman of the Saugus Board of Health and served for thirty years as school and town physician, the newspapers report.

New Deans for Harvard Schools—Dr. Charles Sidney Burwell, Nashville, Tenn., has been appointed dean of the Harvard Medical School and Dr. Cecil Kent Drinker, Boston, of the Harvard School of Public Health. Dr. Burwell was also appointed research professor of clinical medicine. Forty-one years of age, Dr. Burwell is professor of medicine at Vanderbilt University School of Medicine, Nashville. He is an alumnus of Harvard Medical School class of 1919. His appointment is effective in September. Dr. Drinker, professor of physiology at Harvard Medical School, has been assistant dean of the school of public health. He graduated from the University of Pennsylvania School of Medicine, Philadelphia, in 1913, and is 47 years old.

MINNESOTA

Bills Introduced—S 711 and H 683, to amend the laws regulating the practice of massage, propose to reduce the annual registration fee required of such practitioners to \$3. S 704, to amend the workmen's compensation act, proposes to make poisoning by carbon monoxide fumes or its sequelae compensable. S 705 proposes to amend the law relating to the care, treatment and hospitalization of indigent residents of certain counties by permitting the county board of any county in which there is located a hospital designated as a class A hospital by the American College of Surgeons to contract with such hospital to care for and treat indigent residents of the county.

MONTANA

Bill Enacted—S 35 has become a law, supplementing the pharmacy practice act by authorizing the state board of pharmacy to adopt rules requiring registered pharmacists to keep a record of all poisons sold or disposed of, containing the signatures of the purchasers and such other information as the board may require.

Bill Passed—S 146 has passed the senate, proposing to limit the retail sale and distribution of contraceptive devices, prophylactic rubber goods, and articles for the prevention of venereal diseases to licensed physicians, osteopaths, other licensed practitioners of the healing art, and registered pharmacists.

Bills Introduced—H 307 proposes to authorize the commitment to the Montana home for the aged, at the expense of the state of indigent persons totally incapacitated physically and suffering from incurable physical maladies. H 440 authorizes school districts to establish special classes for the instruction of children suffering from disease deformity, physi-

cal or mental defect, or inaptitude H 507 proposes to authorize the establishment of a state hospital for the treatment and care of infantile paralysis victims

NEVADA

Bill Introduced—S 69, to amend the workmen's compensation act, proposes to make occupational diseases compensable

NEW HAMPSHIRE

Bill Passed—H 12 has passed the house, proposing to require a physician or a hospital treating a person suffering from gunshot wounds or other injuries of unusual type to ascertain from such patient the cause of his wounds and to report the facts as soon as possible to the police of the town or city in which such treatment is given

NEW MEXICO

Bills Enacted—The following bills have become laws H 16, authorizing all cities, towns and villages operating under special acts of the legislature to maintain hospitals, sanatoriums and other institutions for the care and maintenance of sick or indigent persons and H 106, prohibiting the possession or sale or other distribution of marijuana except on the prescription of a licensed physician

NEW YORK

Dinner to Dr Whipple—Dr George Hoyt Whipple, dean of the University of Rochester School of Medicine and Dentistry, co-winner of the Nobel Prize in Medicine for 1934 was the guest of honor at a dinner given by the Rochester Academy of Medicine, January 15, at the Oak Hill Country Club Dr Milton C Winternitz dean, Yale University School of Medicine, New Haven, Conn was the principal speaker and many informal tributes were offered to Dr Whipple

Bill Passed—S 20 has passed the senate proposing to amend the workmen's compensation act by (1) authorizing the industrial commissioner to establish a schedule of fees for medical care rendered injured employees, (2) authorizing the commissioner to establish a panel of physicians to render the medical care required by the act, the employee to have the right to select any physician on that panel to treat him, (3) providing that no claim for specialists, consultations, surgical operations or physiotherapeutic procedures costing more than \$25, nor roentgen examinations or special diagnostic laboratory tests costing more than \$10 shall be paid unless such services are rendered in an emergency or have been authorized by the employer or by the commissioner and (4) providing that a physician rendering service to a compensation claimant may recover for his services only under the provisions of the act

Bills Introduced—S 1167 and A 1486 propose to authorize the sexual sterilization of inmates of state homes or hospitals for mental diseases or of state colonies hospitals or institutions for the care of persons defective, deficient or diseased mentally S 1266 proposes to accord to hospitals, physicians and nurses, treating persons injured through the negligence of others, liens on all claims rights of action, judgments, compromises or settlements accruing to the injured persons by reason of their injuries A 1306, to amend the public welfare law, proposes that an indigent sick person may at the expense of the public welfare district in which he resides be treated by a physician of his own choice Physicians so selected by indigent sick persons are to be paid by the district \$1 for office calls, \$2 for house calls and \$25 for obstetric cases A 1339, to amend the education law, proposes to authorize the establishment of colleges of natural therapy The commissioner of education is to prescribe the rules and regulations for the establishment and regulation of such colleges, which are to be authorized to issue degrees to a matriculated student who has completed a four year course of study The bill states that "a doctor of natural therapy shall be deemed to be a person who has successfully taken a course of study prescribed by the regents of the university of the state of New York in a college recognized by it in 1 Hydrotherapy (mineral water) 2 Balneology (mineral bathing) 3 Cibology (preparation of foods for the sick) 4 Dietology (dietetics and metabolism) 5 Hirudology (application of leeches) 6 Hygiene (sanitation, sterilization, antiseptic and aseptic work) 7 Clysmology (lavage of stomach, bladder and colonic irrigation) 8 Laxatology (the relaxation of muscles, tendons joints) 9 Massage (kneading, exercise, under-water exercise) 10 Phlebotomy (application of cupping, plasters salves) 11 Potology (drinks teas in sickness) 12 Rotology (rotation of various parts of the body to relax and release) 13 Electrolysis (removal of hair by electricity) 14 Scalp treatment

(to prevent hair falling and baldness) 15 Physiotherapy (the application of diathermy [sic], ultra violet and other radiations under physicians orders)" The bill is not clear whether or not such a "doctor" would be permitted to practice without the examination and licensure required by the medical practice act

New York City

Hospital News—Dr Ulrich Friedemann, formerly professor at the University of Berlin, gave a lecture at Mount Sinai Hospital, January 14, on "Experimental Investigations on the Blood-Brain Barrier"—Beth David Hospital has acquired ownership of the building now occupied by the Manhattan General Hospital and plans to occupy it in the near future, according to an announcement from the hospital

NORTH DAKOTA

Bills Passed—S 75 has passed the senate, proposing to grant to hospitals supported in whole or in part by private charities and treating persons injured through the negligence of others, liens on all rights of action, claims judgments, compromises or settlements accruing to the injured persons because of their injuries H 311 has passed the house, proposing to amend the medical practice act by (1) making it a misdemeanor for a licentiate to fail to pay the required annual reregistration fee, (2) making a violation of any provision of the medical practice act punishable by a fine of from \$50 to \$500 and/or imprisonment in the county jail for one year or less and (3) providing that any person convicted for a second time of violating any provisions of the medical practice act shall be guilty of a felony and shall be punished by imprisonment in the state penitentiary for from one to ten years at hard labor

OHIO

Bills Introduced—H 163 and H 179 propose to repeal the laws regulating the possession or sale or distribution of narcotic drugs and to enact what apparently is the uniform narcotic drug act

OREGON

Bill Enacted—S 82 has become a law, enacting a new pharmacy practice act The new law seems to prohibit physicians from dispensing drugs, merely permitting them to administer drugs and medicines personally in order to supply the immediate needs of their patients

Bills Passed—The following bills have passed the house H 208, proposing to prohibit the distribution of amylal, luminal, veronal, barbital, acid diethylbarbituric or any preparation or compound containing any of the foregoing substances, except on the prescription of a licensed physician, dentist or veterinary surgeon, and H 377, proposing to amend the laws relating to the state board of health by requiring the secretary of the board to have a degree of doctor of medicine, to have been licensed to practice medicine in the state, and to have had at least five years' experience as a full time public health officer of two years' residence in a recognized school of public health

PENNSYLVANIA

State Tuberculosis Meeting—The annual meeting of the Pennsylvania Tuberculosis Society was held in Pittsburgh, February 19 20 At the medical session speakers were Drs Esmond R Long, Philadelphia, on "The Use of Tuberculin as a Diagnostic Agent with Special Reference to the Purified Protein Derivative", Walter L Rathbun, Cassadaga, N Y, "Measures for Tuberculosis Prevention and Control Among High School Students," and James Burns Amberson Jr, New York, "Is the Hazard of Tuberculosis a Serious One for Nurses?"

Bills Introduced—H 909 proposes to authorize the department of welfare to reimburse hospitals for treating indigent persons injured in automobile accidents H 951 proposes to prohibit physicians, dentists osteopaths chiropractors and "drugless therapists" from "advertising in any manner with respect to the skill of the operator, the quality of the materials or drugs or medicines used, or methods used or practiced." The bill however, is not to prohibit any such person from posting his name and profession on the exterior or interior of the building wherein he maintains his office H 978 to amend the beauty culture law proposes to permit such licentiates to obtain "a certificate of registration to use the electric needle only as a beauty treatment" H 1023 proposes to prohibit the sale or distribution of medicines, drugs or poisons by means of any vending machine or other mechanical device

Philadelphia

Interns' Night—The Philadelphia County Medical Society held its annual "Interns' Night" February 27 with papers presented by Drs William B Wartman, Lankenau Hospital on "Venous Blood Pressure in Some Common Diseases" Walter E. Daniel, Pennsylvania Hospital, "Hematuria" Norman R. Ingraham Jr., Philadelphia General Hospital, "X-Ray Positive, Seronegative Infantile Congenital Syphilis" Glenn A. H. Deibert, Jefferson Medical College Hospital "Value of Excretory Urography" and Amerigo G. Ricciuti, Jefferson Medical College Hospital, "Effect of Cholecystectomy on Hepatic Function"

Pittsburgh

Society News—Speakers at a meeting of the Allegheny County Medical Society, February 19, were Harold V. Smith on "Legal Aspects of Narcotic Administration in Pennsylvania", Drs James R. Watson, "Recent Concepts of Surgical Treatment of Duodenal Ulcer," and Alexander H. Colwell, "The Physician's Attitude Toward Health Insurance"

SOUTH CAROLINA

Bill Passed—H 21 has passed the house, proposing to create a board of chiropody examiners and to regulate the practice of chiropody (podiatry). "Chiropody sometimes called podiatry," states the bill, "shall for the purposes of this act mean the diagnosis, surgical, medical and mechanical treatment of ailments of the human foot, except the correction of deformities requiring the use of the knife, amputation of the foot or toes, or the use of an anesthetic other than local"

TENNESSEE

State Health Department Reorganized—Following the enactment by the state legislature of a law authorizing reorganization of the state health department, Gov. Hill McAlister appointed Dr. Wilson Carter Williams a member of the department staff since 1926 state health officer to succeed Dr. Eugene L. Bishop, who resigned to become full time health officer of the Tennessee Valley Authority. Dr. Bishop has been health officer since 1924 and has been connected with the department since 1916. A native of Nashville and a graduate of Vanderbilt University School of Medicine, he has for several years been assistant professor of preventive medicine at the school and is now president of the American Public Health Association. Dr. Williams graduated from Vanderbilt in 1925. In 1926 he joined the health department as health officer of Williamson County and has since served as director of the field technical staff and director of county health work. In accordance with the new law the governor has also appointed a board of health of nine members. Six physicians are on the board: Drs John M. Lee, Nashville, chairman, John C. Ayres, Memphis, John R. Thompson Jr., Jackson, Ernest M. Fuqua, Pulaski, Claude P. Fox Sr., Greenville, and William K. Vance Jr., Bristol. Other members are Oren A. Oliver, DDS, Nashville, Leslie F. Mitchell, Nashville, a pharmacist and Mrs. Ferdinand Powell Johnson City, representing jointly the Tennessee Council of Parents and Teachers and the Tennessee Federation of Women's Clubs.

TEXAS

Bill Introduced—S 312, to amend the medical practice act, proposes to permit Christian scientists and other persons whom the present act permits to apply the principles tenets or teachings of their church in ministering to the sick, to charge for their services.

Three County Health Unit—A three county health unit including El Paso, Hudspeth and Culbertson counties has been established under the supervision of Dr. Thomas J. McCamant, health officer of El Paso County. Dr. George M. Dunne will be assistant director of the unit at Sierra Blanca and Dr. Wiley Smith at Van Horn.

UTAH

Bill Passed—S 170 has passed the house proposing to accord to hospitals, treating persons injured through the negligence of others, liens on all rights of action claims, judgments, settlements or compromises accruing to the injured persons by reason of their injuries.

VERMONT

Bill Introduced—H 237 proposes to so amend the medical practice act as to exempt from its provisions persons licensed to practice naturopathy under the laws of this state. The present state law, however, contains no provision authorizing the licensing of naturopaths as such.

WASHINGTON

Bill Passed—S 137 has passed the senate, proposing to authorize two or more adjacent counties to establish sanatoriums for the care and treatment of persons suffering from tuberculosis.

Bills Introduced—H 449 proposes to require as a condition precedent to the issuance of a license to marry that both parties to a proposed marriage present a physician's certificate that they are free from contagious or infectious venereal diseases, mental illness or defects. H 492 proposes to authorize the state insurance commissioner to license persons, associations and corporations to engage in the business of issuing contracts for the furnishing of medical, hospital, nursing and dental care or for any other necessary services contingent on sickness, accident or death.

WEST VIRGINIA

Bills Introduced—H 323, to amend the workmen's compensation act, proposes to prohibit an employer from entering into a contract with any hospital to render medical, dental or hospital service or to give medical or surgical attention therein to any workman for an injury compensable under the compensation act. The bill further proposes to prohibit an employer from requiring any workman to contribute directly or indirectly to any fund for the payment of medical, surgical, dental or hospital services for any compensable injury. H 362 proposes to require every child entering any public or private school after Sept. 1, 1935, to file with the appropriate county superintendent of schools a certificate of health from a licensed physician stating that the child is free from all communicable and contagious diseases. No child found to be suffering from any communicable disease in an infectious stage is to be permitted to attend school. H 364 to amend the workmen's compensation act proposes (1) to require the compensation commissioner to pay such sums for medical, surgical and hospital treatment as may be reasonably required to relieve an injured employee, the present law limiting such payments to \$800 and (2) to eliminate such portions of the present law as prohibit the commissioner from paying for medical and hospital services furnished an injured workman if the workman is entitled under a contract connected with his employment or by reason of a subscription list to receive medical, surgical and hospital treatment without further charge to him. H 331, to amend the workmen's compensation act, proposes to make silicosis compensable. The bill defines silicosis as an insidious fibrotic disease of the lung or lungs due to the prolonged inhalation and accumulation sustained in the course of and resulting from [the] employment of minute particles of dust containing silicon dioxide (SiO_2) over such a period of time and in such amounts as result in the substitution of fibrous tissue for normal lung tissues. The bill proposes to create a 'silicosis medical board' to consist of three licensed physicians, to which the compensation commissioner is to refer all claims for compensation on account of silicosis. The board is to investigate, examine and report its findings to the commissioner.

WISCONSIN

Officers of Board of Health—Dr. Mina B. Glazier, Bloomington, for eleven years a member of the state board of health, became president at the annual meeting, January 31. Dr. Joseph Dean Madison, was reelected vice president and Dr. Harry H. Ainsworth, Birchwood, named president-elect.

Bills Introduced—A 267 proposes to create a state medical grievance committee, to consist of the state health officer, the secretary of the state board of medical examiners, and the attorney general. This committee is to hear, investigate and act on practices of licensed physicians, osteopaths or chiropractors that are inimical to the public health. The committee is to have power to warn and to reprimand, and to institute criminal action or action to revoke the licenses of offenders. A 285 proposes to accord a right of action for prenatal injuries to the child injured and to any other person sustaining damages thereby.

HAWAII

Portraits Presented—Three portraits were recently presented to the library of the Honolulu County Medical Society of the following physicians: Gerit P. Judd, one of the first physicians to come to the islands in the days of the missionaries and the grandfather of Dr. James R. Judd, a member of the society; John S. McGrew, founder of the Hawaiian Medical Society and known in history as the "father of annexation," and Georges Philippe Trousseau, son of Dr. Armand Trousseau, author of many standard medical works. Dr. Bernard Myers of the Royal College of Physicians, London, addressed the society recently.

GENERAL

Diploma Stolen—Dr Charles E Boylan, Chicago, reports that his diploma from the University of Illinois College of Medicine, issued in 1931, has been stolen

Senate Committee Tables Birth Control Bill—By a vote of 9 to 6 the Senate Committee on Judiciary declined to report favorably Senate Bill 600 introduced by Senator Hastings, Delaware, proposing to relax the restrictions of the Criminal Code concerning the distribution of information on contraception. The corresponding committee of the House of Representatives tabled a similar bill introduced by Representative Pierce Oregon, H R 2000

Medical Bills in Congress—A subcommittee of the Senate Committee on Commerce began hearings, March 2, on Senate 5 a bill to prevent the manufacture, shipment and sale of adulterated or misbranded food drugs and cosmetics to regulate traffic therein and to prevent the false advertisement thereof *Changes in Status* H R 6623 the Interior Department appropriation bill has passed the House. Among other things, it authorizes an appropriation of \$3,534,620 for the conservation of health among Indians an appropriation of \$20,000 for a clinical survey of tuberculosis, trachoma and venereal and other diseases among the Indians and an appropriation of \$295,000 to provide for the medical and sanitary relief of the Eskimos, Aleuts Indians and other natives of Alaska

News of Epidemics—At a Trappist monastery at Gethsemane, Ky, twenty-seven cases of influenza with seven deaths, occurred among the eighty residents in February—Fifty students of Colgate University, Hamilton, N Y were reported to be ill with German measles February 26—Newspapers report the presence of epidemic meningitis among transients in various cities. At Knoxville Tenn five cases have occurred since the first of the year and outbreaks have also been noted in Cincinnati Little Rock Ark Memphis, Tenn and the District of Columbia—Deaths of ten new-born infants in the obstetric section of Holy Name Hospital, Teaneck N J, during January, have been traced to a streptococcal infection the New York Times reported February 16—Students at the Brooks School, North Andover Mass were quarantined February 1 because of an epidemic of mumps within the school—Newspapers reported an epidemic of scarlet fever in Hammond and Gary Ind during January. January 28 sixty cases were under quarantine and three deaths had been reported. Public gatherings were closed to children under 16

Society News—The Association of Record Librarians of North America will hold its seventh annual session in San Francisco October 28-November 1—The American Pharmaceutical Association will hold its eighty-third annual meeting in Portland Ore, August 5-10 with headquarters at the Hotel Multnomah—The Association for the Study of Allergy and the Society for the Study of Asthma and Allied Conditions will hold a joint meeting in Atlantic City June 10-11—The midwestern section of the American Congress of Physical Therapy will hold a one day session in Madison Wis March 12. The morning will be devoted to clinics at the Wisconsin General Hospital and the afternoon to addresses. Among speakers will be Drs John Stanley Coulter, Chicago, on Physical Therapy in Relation to Arthritis. Frank H Ewerhardt St Louis. Physical Therapy in Relation to Orthopedic Surgery, and Harry C Rolnick Chicago. Status of Electrosurgical Resection—The American Dietetic Association will hold its annual meeting in Cleveland, October 29-31—The tenth annual meeting of the American Association for Adult Education will be held in Milwaukee, May 20-22—The International Association for Dental Research will hold its thirteenth annual meeting in Chicago March 16-17. William J Gies Ph D of Columbia University New York is secretary of the association. Interested physicians are invited to attend—The annual informal dinner and general conference of diplomates of the American Board of Obstetrics and Gynecology attending the annual session of the American Medical Association at Atlantic City will be held at the Hotel Travmore, Wednesday evening, June 12, at 7 o'clock—Dr Carl R Crutchfield Nashville, was chosen president-elect of the Mid-South Postgraduate Assembly at the annual meeting in Memphis, February 12-15, and Dr Henry King Wade, Hot Springs Ark, was installed as president. Dr Arthur F Cooper Memphis was reelected secretary and vice presidents elected are Drs Julian G Price, Dyersburg Tenn, Billy S Guyton, Oxford Miss, and Rufus B Robins Camden Ark—The annual meeting of the Federation of American Societies for Experimental Biology will be held in Detroit April 10-13 with headquarters at the Hotel Statler and

scientific sessions at the Masonic Temple. Further information about the meeting may be obtained from the secretary, Henry A Mattill, Ph D, State University of Iowa, Iowa City

CANADA

Osler Memorial Day—The Hamilton (Ont) Academy of Medicine inaugurated an Osler Memorial Day, February 27, the anniversary of the publication of Sir William Osler's first paper, "Christmas and the Microscope." The morning of the day will be spent at Hamilton General and St. Joseph's hospitals in demonstrations in various branches of medicine, the afternoon at Mountain Sanatorium in demonstrations of the therapy of tuberculosis. At a luncheon Dr Thomas B Futcher Baltimore a former student of Osler's, will make an address and late in the afternoon there will be a pilgrimage to various spots associated with Osler's early life. At the luncheon a prize will be presented to the writer of the best essay entitled "The Life and Work of Osler" in a competition open to third and fourth year students of McMaster University

Society News—Forty-seven cases were presented by members of the staff of the Montreal General Hospital at the meeting of the Montreal Dermatological Society at the hospital, Dec 1, 1934—Dr John S McEachern, Calgary, Alta, president of the Canadian Medical Association, and Dr Thomas C Routley, Toronto, general secretary, are touring the provinces of Canada addressing medical societies on the advantages of closer organization—The Academy of Medicine of Toronto offered a special course of lectures on diseases of the respiratory tract January 7-11. Speakers were Drs Wilfred P Warner, Harold C Parsons Jabez H Elliott, Norman S Shenstone, Ernest A Broughton, Thomas A Davies, Ambert H Veitch, Wilbur J Cryderman George C Anglin and Robert M Jones. The society had a library and historical night, January 8, at which Dr Harry B Anderson presented an address on the life and times of Dr James Macaulay (1759-1822)—St Mary's Hospital, Montreal, erected at a cost of \$1,250,000, was recently dedicated. The new hospital is an eight story building with 200 beds

FOREIGN

Funds Sought for Harvey Memorial—The Harvey Memorial Committee is seeking a fund of £2000 to complete the reconstruction of Hempstead Church, Essex, where William Harvey is buried. An appeal in 1930 brought sufficient funds to rebuild about two thirds of the tower of the church, which collapsed in 1882. The Harveian Society of London in 1931 raised a fund for the reconditioning and rehanging of the church bells when the tower is completed. Donations are invited from the medical profession, they should be made payable to the Harvey Memorial Fund and sent to Dr G de Bec Turtle, Royal College of Physicians, Pall Mall East, London, S W 1

Prize for Essay on Venereal Disease—The council of the British Medical Society for the Study of Venereal Diseases announces a prize of £18 to be awarded for the best critical review dealing with any venereal disease considered from any angle. The essay selected for the prize will become the property of the council and in addition the council is understood to be at liberty to publish in the *British Journal of Venereal Diseases* any paper other than the one to which the prize is awarded. Contributions of about 6000 words should be typed on one side of the paper, with a quarter of a page as a margin and sent to the secretary of the society, 43 Queen Anne Street, London W 1 before July 31, 1935

Government Services

Examinations for Army Medical Corps

The War Department announces a competitive examination for the purpose of qualifying physicians for appointment as first lieutenants in the Army Medical Corps to fill existing and anticipated vacancies during the fiscal year 1936. Graduates of recognized medical colleges who will have completed internships in approved hospitals before July 1935 are eligible, provided they meet the physical standards and will not be more than 32 years old at the time it is possible to tender them a commission. Applicants will be authorized to appear before examining boards convened throughout the United States. Information and application blanks may be obtained from the Adjutant General War Department Washington D C. Applications must be filed by March 25

Psychology and Religion

The presidential address of Dr David Forsyth to the Section of Psychiatry of the Royal Society of Medicine on Psychology and Religion, published in the *Times* provoked a vehement reaction among religious persons. He maintained that the new spirit of toleration between science and religion, which led some to believe that there was no inherent conflict between the two, was not supported by modern psychology, which showed their incompatibility more than ever. Psychoanalytic research traced many religious ideas back to unexpected sources in childhood. The 'voice of conscience' proved to be the voice of the father as heard years ago in childhood. Similarly, the attributes attached to God by adults were those which had been experienced in the father. The sense of sin and guilt which showed itself in children about the age of 7, always was a conflict between the child's inclinations and its parents' wishes especially with regard to bodily functions.

Belief in a soul and the hope of immortality was taken by Christianity from primitive religions. Belief in a soul was general among savages and arose from dreams in which the dead were seen. Sexual feeling entered into some aspects of religion, and religious conversion represented a disorder of sexuality, in adolescents the new tide of sexual feeling being checked in its usual course was deflected into religion. Certain curious aspects of the religious life could be explained in the light of the sadomasochistic impulse. The sadism of Christianity was evident in the cruelty in the past to the unorthodox. In Islam, sadism was stronger, Mahomet's gospel was spread by the sword. On the other hand, Christ's teaching, as in the Sermon on the Mount, was essentially masochistic and had always appealed more to women, with their inborn masochism, than to men, with their inborn sadism.

The most distinctive characteristic of religion was belief in the supernatural, which science had failed to discover. It was claimed that religion detected the supernatural world by mystical methods, which alone were suitable for things spiritual. If the sensory world known to science was real, why, it might be asked, should not the spiritual world, known to religion be real also? The reply of psychology was that all processes of thinking were of two kinds—pleasure thinking and reality thinking. Pleasure thinking was well known under the name of 'imagination' and showed itself in dreams and day dreams. It was employed in all creative artistic work, but psychology allocated it to the world of fantasy, where the writ of nature did not run. The mysterious business of gods and spirits was an example of childish projection on a colossal scale.

The conflict between religion and science represented the difference between psychic and objective truth. Of the two psychic truth was the more primitive and expressed the deepest needs of the individual. Objective truth was the more highly acquired and served in subduing the forces of nature in the interests of the individual. Neither could be disregarded, and the two must be directed to a common end. The need was to cease applying pleasure thinking to the illusory aims of religion and to use it in advancing science.

The immediate result of the publication of this address was a letter to the *Times* from six medical psychologists expressing surprise at its appearance in the daily press because presidential addresses are often intentionally provocative, are not subject to discussion, and therefore should not receive such uncritical publicity. The signatories added that it should not be assumed that the large audience which heard the president's able paper

was in agreement with his startling conclusions. In fact there were in this country few medical psychologists who would subscribe to them. The pediatrician G F Still was another critic. He said in the *Times* that it must be remembered that psychology rests more largely than any other department of medicine on theory and speculation. As to the cruelty to which Dr Forsyth referred the psychology of Christianity must be read not in the behavior of those who call themselves Christians but in the teachings of its founder. He also repudiated the statement that there is any masochism in the Sermon on the Mount. The joys there described are to be in the hereafter, which will make amends for righteous suffering here. Dr Matthews, dean of St Paul's, also dealt with the subject in an address. The essence of the attack of psychology on religion he wrote, was that religion was a projection of man's hopes and fears. This was not a new criticism, but in our time the idea that God was a projection had been elaborated by psychologists. In recent times there had been a remarkable development in every science, particularly physics, and one of the results had been to give scientists a clearer view of their limitations. To the extent that psychology claimed to be a natural science, that limitation applied to it. Every argument that claimed religion to be an escape from reality was a question-begging argument. Those who used it had in mind a merely materialistic view and everything beyond that was taken for granted as unreal and illusory. He admitted that fantasy did play a part in some religious experience but that was an aberration of religion. He finally pleaded for cooperation between psychology and religion. Each could aid the other in the establishment of mental health.

Records of Longevity

For the twentieth year Mr C B Gabb has reviewed the longevity figures recorded in the *Times* during the past twelve months. On the front page of the *Times* during 1934 the deaths of 460 persons 90 years old and over have been recorded. Of these 127 were men and 333 women. Of the latter, 207 were married. The total number of nonagenarians who died in the last twenty years was 7,305, of whom the majority were married women giving the yearly average of 365. The centenarians who died in 1934 numbered eleven against twenty in 1933. Only one of the eleven was a man, and six of the women were married. The senior was a married woman aged 105. In Ireland the burial of Mrs Catherine Buckland, aged 123, in Ballycommon churchyard North Offaley, Kings County, was recorded. Edward Cooper, born in Dublin, Sept 18, 1818 died in California. He had lived in the United States eighty years having migrated in the early gold rush. Franz Baldast, believed to be the oldest man in Austria, who recently carried off first prize at a village dancing competition, died at 110. Mrs Maria Greenwich, the oldest woman in western Canada, died at the age of 109 at Edmonton, Alta. A woman of the same age, Mrs Scariffe, died at Glengarry, Australia. William Freeman, aged 104 the last Crimean veteran in Australia, died at 104, and another Crimean veteran, James Crawford, died at the same age in New Zealand. Frau Maria Schoepperle, the oldest woman in Germany, died in Barder at the age of 106. Mrs Trainer died at Newry, Ireland at the same age.

Epidemic of Malaria in Ceylon

An epidemic of malaria of unusual severity has broken out in Ceylon. The area involved is 5,000 square miles in extent, with a population of 3,500,000. Within three weeks 500,000 persons were attacked. The medical department of the government has engaged 320 additional physicians, apothecaries and inspectors for malaria work. A sum of 5,000,000 rupees has been set apart for an antimalaria campaign directed by a special officer from abroad, preferably from the Ross Institute, and for a housing scheme. The registered deaths from malaria in the

Northwestern Province were as follows, compared with a normal monthly average of 700 January, 7,038 December, 3,463 November, 1,394 In the January total, 5,468 of the 7,038 victims were children under 14 But reports exceed these registered figures and no authentic figure is available for the total number of deaths from malaria between November and January, though it is held that it must have exceeded 30,000 A new drug, atabrin-musonat, has been used in the General Hospital, Colombo and is believed to have remarkable results in the absence of relapses

Malaria has long been endemic in Ceylon, and the present epidemic has caused no surprise to malariologists It is explained as follows Normally endemicity is low in the southwest of the island Owing to the southwest monsoon, the rainfall varies from 100 to 200 inches a year The flow of water in the rivers is therefore abundant and the flushing keeps them free from larval breeding In this area the endemicity is low But in the remaining part of the island about two thirds of the whole, the conditions are favorable for the breeding of the mosquito *Anopheles culicifacies* The endemicity is high, the spleen rate varying from 40 to 60 per cent and more The inhabitants of this area are relatively immune and therefore malaria does not become epidemic The cause of the present serious epidemic is that the prevailing rains failed to supply the usual amount of water and conditions arose which favored the breeding of *Anopheles culicifacies* in pools along the beds of the rivers and streams in the healthful part of the island The inhabitants of this area having little acquired immunity, readily succumbed to the increased density of malaria carrying mosquitoes The predominant infection is benign tertian (57 per cent), while quartan comes next (33 per cent) The malignant tertian is rare (10 per cent)

Telephone Amplifier for the Deaf

A problem for telephone engineers has been to produce at the receiving apparatus speech of the same volume as that which has left the transmitter, and British engineers have solved it An announcement is now made that the postoffice has made full provision for meeting the needs of deaf persons Its engineers have produced a variable amplifier to increase sound to the degree required It can be hired at a cost of \$250 for three months Another instrument which has been successfully experimented with is a loud speaker telephone, which is expected to be soon available to the public

PARIS

Feb 4, 1935

Students Protest Against Foreigners

During the last few days of January and until February 2 the strike of medical students in the chief university centers of France filled many columns in the daily papers It ended temporarily in Paris after a delegation had presented the students' protests to the minister of public instruction, issuing an ultimatum that a truce would be declared until March before taking up the strike again

To understand the students' claims, one must recall that in the medical schools and also in the other departments of the universities over 20 per cent of the 38,000 students are foreigners Many of these, after graduation, remain in France, where all the professions are overcrowded The students maintain that too many privileges are accorded foreigners, especially in the medical schools Many foreigners are admitted who, when matriculated aim only to have a so-called honorary diploma called *Diplome universitaire* bestowed on them This sort of diploma does not require a preliminary two years of study leading to the bachelor of arts degree The latter is indispensable for those who wish to receive a state diploma entitling

them to practice any profession, especially medicine, in France The claim is made that a change from the honorary to the legal diploma is made too easy for foreigners in the provincial universities According to the "Armbruster law" no one will be admitted, on credentials, to the fourth year of the medical school, as has been the case in the past, but will be compelled to spend seven years in medical studies, in addition to a bachelor of arts degree, before being eligible to a state license Further more, no foreigner will be permitted to practice medicine in France who has not been naturalized A certain number of exceptions, according to this law, can be made to this last requirement, in the case of foreigners from countries which do not demand naturalization of French citizens in order to have the right to practice The students maintain that the Armbruster law is a great protection against foreigners remaining in France as physicians but that it is not being enforced and that too many foreign undergraduates are allowed to occupy internships and replace practitioners temporarily One of the strikers' demands was a modification of this law, to the effect that any foreigner desiring to study medicine must have been naturalized for a period of ten years before entering a medical school In Paris, hundreds of students milled around the medical school, shouting 'Down with the foreigners' A few of the twenty-five or so American students were roughly shoved away from the school entrances and told that all classes had been suspended temporarily All lecture rooms and laboratories were ordered closed by the dean, Professor Roussy The strike lasted only a few days but will probably be called again unless drastic measures are taken by the authorities to prevent the crowding out of French students by foreigners

The Dangers of Arteriography

At the January 9 meeting of the National Surgical Society, some cases were reported which called attention to serious complications and even fatal issues that can occur as the direct result of the use of arteriography

Desplas and Reboul reported the case of a woman, aged 67, who had an ingrown toenail associated with evidence of an obliterating endarteritis The femoral arteries of both limbs were injected with a 'tenebryl' solution, the French substitute for the opaque solutions used in arteriography and containing 45 per cent of iodine Twenty-four hours later, reddish bullae and cyanotic areas appeared on the leg where the presence of an obliterating endarteritis had been previously noted These local lesions and the pains in the left extremity disappeared during the following days The patient, after marked dyspnea, died the night of the eighth day The necropsy revealed only atheromatous plaques in the principal arteries

In a second case, a man aged 56 was admitted to the hospital with a diagnosis of intermittent claudication of five years duration Ten cc of thorium dioxide sol was injected into the femoral artery but some of the solution escaped into the tissues around the upper end of the femoral artery at the point of injection This accident was followed by an extensive gangrenous infection of the cellular tissue, showing that thorium dioxide sol, for which many advantages have been claimed, acts as a caustic There were no further complications in the second case Senèque and Benoit reported a case of diabetic gangrene, involving one toe of the right foot, with a definite line of demarcation Twenty cc of "tenebryl" solution was injected into the femoral artery of the corresponding limb The gangrene began to extend rapidly from the toe to the dorsum of the foot necessitating immediate amputation at a higher level The patient became comatose and died forty-eight hours later The tibial and peroneal arteries revealed marked calcification of their walls and the lumen was occluded by a well organized thrombus The latter changes could not be ascribed to the 'tenebryl' injection

Bazy and Reboul added the case of a man, aged 54, who complained of attacks of severe cramplike pain, preceded by a feeling of numbness and cold in both upper extremities. There was an ulceration and cyanosis at the tips of two fingers of the right hand. Twelve cc of tenebryl was injected into the lower end of the brachial artery of this arm. Immediately following the injection the entire upper extremity became very cyanotic and there was complete anesthesia. A few days later a mummification of the forearm occurred, which will necessitate an amputation. The injection had evidently been followed, as in Leveuf's case, by an arterial spasm and gangrene.

These accidents in arteriography are analogous to the lesions seen in those who have been exposed to short circuits in electrical work.

Mondor reported that out of ten arteriographies, without sequelae in any case, the method was of diagnostic value in only one. This was an aneurysm of the popliteal artery in which the arteriography revealed a series of small aneurysms above the larger sac.

Sorrel believed that if one employed thorium dioxide solution instead of tenebryl, with a correct technique there was no danger of an accident following an arteriography.

Huet reported a case of extensive gangrene of the arm following injection into the lumen of the brachial artery of a hypertonic (20 per cent) saline solution. He believed that the endothelium of arteries does not tolerate any solution that can be regarded as a foreign body.

The First "Skyscraper" Hospital in Europe

The new Beaujon Hospital has just opened its doors in Paris. An event that would attract little attention in the United States is hailed here as the beginning of a new era in hospital construction. The majority of continental hospitals are composed of a group of one to, at the most, three story buildings, scattered over a relatively large area. The new Beaujon Hospital is eleven stories in height and has a capacity of 1,100 beds with a large outpatient department. There are only fourteen beds in each ward, and four of such wards form a service under the charge of a single attending physician. The laboratories and rooms for research work are in immediate proximity to each service. The cost of construction has been \$4,500 per bed and it is hoped that the cost of maintenance may be materially decreased through centralization in one building.

Immunization of Large Groups Against Diphtheria

For years diphtheria has been increasing in Germany, and particularly in certain industrial sections. One of the principal foci was the Landkreis of Aix-la-Chapelle. Whereas in this area the morbidity in former years ranged between eighty and a hundred cases, it rose in 1931 to more than 500 cases in 1932 to almost 700 cases, and in 1935 to 1,165 cases. There was a corresponding increase of the mortality figures. Small communes in which previously only two or three persons a year, on an average, contracted diphtheria notified, last winter, from 300 to 400 cases. The customary method of combating the disease (closing of the schools, disinfection of dwellings, isolation of patients and bacillus carriers) proved of little avail. At this juncture the ministry commissioned Professor Gundel of the Preussisches Institut für Infektionskrankheiten "Robert Koch," Berlin to inaugurate an inquiry and protective inoculation on a large scale. A portable laboratory was established and the cooperation of the general public was enlisted. In the district of Aix-la-Chapelle, 45,000 children were inoculated in the rural sections, and 35,000 in the urban center. In Duisburg 82,000 children were inoculated during 223 periods appointed

for vaccination. This required the services of nine municipal physicians, fourteen *assistentärzte* and many voluntary private physicians. Each physician vaccinated from 140 to 150 children per hour. Seventeen hundred teachers helped with the filling out of questionnaires and filing cards, and in explaining matters to the parents. There were several hundred other helpers. The funds for the purchase of the large quantity of vaccine material were supplied by welfare organizations. The success of these measures was notable. In this district around Aix-la-Chapelle, diphtheria was virtually eradicated. Communes that formerly notified from sixty to seventy new cases every week register today from two to three cases at the most, and it is possible that these persons, for some reason, escaped being vaccinated. The lives of hundreds of children have been saved in recent months. At present, 7,000 children are being vaccinated in Göttingen.

It is not certain whether such comprehensive protective inoculations should be carried out in the whole Reich. Gundel does not favor such action, as not all parts of the Reich are threatened with diphtheria epidemics. Furthermore, it is impossible to comply with all the requests for vaccine material addressed to the central authorities, since all the material available for the next few months has already been allocated. It has been emphasized, too, that it is not advisable (in fact, that it is subversive of the action of such inoculations) to employ widespread inoculations if they are to be carried out in a restricted manner—that is if only a small percentage of the children menaced by the disease are inoculated. The minister of the interior has therefore ordered that no vaccinations of a restricted portion of the child population shall be undertaken. If the disease becomes so widespread as to make the inoculation of all children desirable, a report should be sent to him, in order that he may be in a position properly to distribute the available vaccine material and to provide for efficient application of the inoculations.

The Non-Aryan Physicians in Germany

Until recently the number of Jewish physicians, and particularly the number serving in the *kranken-kassen*, was not accurately known. Now the *Reichsarztregister* (register of federal physicians) has collected authentic material, which has been published by the statistical department of the *ärztliche Spitzen-organisation* (medical federation). According to these computations there were 6,488 Jewish physicians in Germany at the beginning of the new regime. As the total number of physicians was about 50,000, the Jews constituted 13 per cent of the total. Berlin alone had 3,000 Jewish physicians. During the year 1933 the number of non-Aryans diminished by 578 through emigration—not quite 10 per cent. Their number was thus reduced to 5,910. Of this number 3,641 have been admitted to panel practice. Excluded from such practice were 1,667 non-Aryan physicians (of this number 468 have removed to some foreign part). On the other hand, 1,199, in spite of loss of panel practice, have continued their activities in Germany. The remaining 1,070 physicians, who have not been admitted, are those who, according to the new regulations are refused admittance further by physicians of advanced age and by those who even formerly, for some reason or other had never been admitted to panel practice. Of this number, 110 have migrated to some foreign part.

Of those who have remained in Germany 3,503 are general practitioners and 2,407 are specialists, distributed in part as follows: 457 dermatologists, 405 internists, 274 gynecologists, 243 pediatricians, 221 otorhinolaryngologists, 198 ophthalmologists, 187 neurologists, 134 surgeons.

The number of dermatologists and venereologists is especially large. Berlin alone has 188. Also in certain other districts this specialty has a large representation. The same is true of

the internists. In Berlin alone there are 2,617 resident Jewish physicians, 1,711 general practitioners and 906 specialists.

Out of a total of 32,000 panel physicians in the spring of 1934, 3,641 (11.4 per cent) were non-Aryan. Constant changes in the various districts, however, caused marked fluctuations. The non-Aryan panel physicians have an especially large representation in the metropolitan cities.

Before the changes of 1933, the number of Jewish women physicians was 572. The number has now been reduced to 529, nearly 50 per cent of whom (276) reside in the district of Berlin.

According to the computations of the Aerzteverband, the non-Aryan physicians admitted to panel practice amount to 60 per cent, which corresponds to the percentage among the physicians as a whole. But the fact is often lost sight of that the Aryan physicians not admitted to panel practice have numerous other positions open to them (as health officers, for example), whereas all such positions are closed to physicians of Jewish extraction.

Mountain Sickness

Comprehensive experiments carried on in the Institut für Luftfahrtmedizin in Hamburg, concerning which Dr. Anthony recently reported before the Wissenschaftliche Gesellschaft für Luftfahrt, have shed considerable light on the cause of mountain sickness. Comparative tests were applied to thirty healthy persons. The examinees were placed in the pneumatic chamber of the institute, where they remained until the first demonstrable signs of mountain sickness appeared. In the same manner, experiments with the inspiration of air mixtures deficient in oxygen were carried on. It was found that solely oxygen deficiency is responsible for the appearance of mountain sickness. By the addition of carbon dioxide and oxygen to the air breathed, mountain sickness can be prevented.

Lamblia and Amebiasis

On the occasion of the Congresso di studi coloniali, in Naples, Generale Medico Dott. Rizzuti presented a communication on lamblia associated with amebiasis. The frequent observation of *Lamblia intestinalis* in the feces of persons with enterocolitis in the absence of other specific protozoan or bacillary forms had awakened the suspicion that *Lamblia intestinalis* also exerts a pathogenic action, whereas this organism has been regarded as a harmless saprophyte. Lamblia in 1931 was found in Sicily, in connection with an epidemic of dysenteriform enterocolitis discovered in troops stationed there. Likewise in Sardinia, in 1933, forty-three carriers of *Lamblia intestinalis* were found in a division of troops at Magdalena.

Lamblia may be of pure or mixed types. The pathogenesis is not yet clear. It is probable, however, that it involves a traumatic action on the intestinal epithelium following which an anergy of the epithelium itself and the adjacent organs develops. There are no pathognomonic signs. The diagnosis is based chiefly on examination of the feces.

When *Lamblia intestinalis* becomes localized in the biliary tracts there are symptoms of cholecystitis and in such cases examination of the bile according to the Meltzer-Lyon technic will not reveal the true nature. Application of the therapeutic test is sometimes valuable. The administration of naphthalene, according to the Sorge method, usually causes the organisms to disappear from the bile.

The association of lamblia with amebiasis was found in Tripoli and Cyrenaica and also in concentration camps for prisoners, during the war. In all the cases marked persistence of the disorder, resistance to treatment and frequency of recurrences were observed.

At present there is no true specific for intestinal lamblia.

Tuberculosis of the Bones and Joints

Before the Unione internazionale contro la tubercolosi, Professor Putti discussed tuberculosis of the bones and joints and its treatment. He contended that the division into medical and surgical types has no theoretical foundation or practical utility. The clinical problem of tuberculosis is today dominated by a single conception—the relation to the constitution. Hence the patient with osteo-articular tuberculosis is treated as a patient in whom the skeletal localization is secondary to other localizations, usually pulmonary. The conception of antagonism between pulmonary and extrapulmonary tuberculosis has not yet been demonstrated. The two localizations do not exert any mutual influence on each other—at least not to an appreciable extent.

It is always necessary to consider a general and a local therapy. As there is no specific, the general treatment is based on the conception of strengthening the defense forces. Immunotherapy is still in an experimental stage. The speaker stated that he had secured good results with the antigen of Boquet and Negre. Gerson's diet acts well on the digestive apparatus. The idea of a specific solar action has been abandoned. Today heliotherapy and climatotherapy are regarded as stimulative therapy that acts not only through the radiant energy of the sun but also by virtue of a complex of surrounding physical elements. To prevent any possible habituation to the stimulus it is necessary to change from one climate to another, especially in treating children. Operative treatment properly so called is limited to certain general principles, for example, resection should not be resorted to in persons who have not completed their growth.

For *juxta-articular* or *para-articular* foci that are easily accessible, early intervention is indicated, as regards the hip immobilization pure and simple. Amputation and disarticulation are sometimes necessary. Ankylosis constitutes the ideal outcome of osteo-articular tuberculosis. Arthrodesis may lead rapidly to such results but cannot replace bed rest and immobilization with a plaster cast.

Supervision of Houses of Prostitution

With the new year and the need of providing for physicians charged with the supervision of houses of prostitution, the minister of the interior has called the attention of the prefects to the duties that devolve by law on this class of health officers. They must gratuitously pay the first visit to the women who are in houses of prostitution; they must pay biweekly visits and special visits whenever there is occasion for it. They inspect the hygienic conditions of such houses and report promptly to the provincial physician all cases of infectious and parasitic disease, in addition to venereal disease. The treatment of venereal disease (and particularly syphilis) that is not in the contagious stage and does not require the removal of the woman is gratuitous. If the treatment cannot be given in the houses, and if a woman is unable to avail herself of a specialist, the provincial physician may authorize the visiting physician to give her private treatment on the basis of the minimal tariff. Every three months the visiting physicians of a city will be assigned different houses, according to a definite rotation scheme.

Congress of Urology

The Congress of Urology was held recently in Rome, the chief topic being 'Study on Renal Functioning, with Especial Reference to Urinary Surgery.' Dr. Migliardi spoke on renal function tests. He commonly uses the phenolsulphonphthalein test, to which he does not ascribe, however, as much value as do some authors. He discussed the surgical prognosis in relation to the renal function tests. The criterion furnished by the tests commonly employed is only relative and it is not

possible to establish absolute limits of operability. With regard to the phenolsulphonplithralem test, the speaker observed that in some cases one can operate with reasonable assurance even though the eliminations are poor (20 per cent, or even 10 per cent or less). Renal function tests, however, together with other factors, constitute a notable aid in formulating a prognosis.

Medical Units in Somaliland

During his recent journey through Somaliland, the king of Italy inaugurated at Chisimaio a hospital equipped with the most modern services. There are today in Somaliland five hospitals. One is at Mogadiscio and is comparable to a large continental hospital, the other four are at Villaggio Duca degli Abruzzi, Alula and Dante and Chisimaio. In addition to these hospitals there are ten medical stations in villages. There are also eighteen infirmaries in the remote parts of the colony, and these infirmaries have control of twenty five medical stations. Owing to the nomadic character of the natives, their marked resistance to disease and their disinclination to enter a hospital it is to the infirmaries and to the medical stations that they resort by tens of thousands.

In addition, there is an agricultural colony for leprosy persons. A large number of militarized mobile units furnish sanitary protection at the borders and in the forests.

Regular courses are held for the training of native nurses and midwives.

Physician Elected President of Tokyo University

Following the resignation of Kiheiji Onodera, president of the Tokyo Imperial University, the fifth presidential election took place, December 15, in the great hall of the institute. Prof. Dr. Mataro Nagayo, dean of the medical department of the university, was elected the next president by the majority of 98 out of 164 votes. He was born in 1878 and had been director of the Infectious Disease Research Laboratory from 1919 to 1933. He was also president of the Cancer Research Institute. Of his many achievements, the determination of the cause of tsutsugamushi disease is the most valuable. Chiefly because of his devotion for many years, the Infectious Disease Research Laboratory became one of the two biggest institutes of the kind. His present post of dean will be taken over by Prof. Dr. Hisomi Nagai, professor of physiology in the university.

University Hospital Destroyed by Fire

A fire broke out in the evening of January 1 in the main building of the hospital attached to Kumamoto Imperial University of Medicine. It spread to the x-ray and gynecologic sections and raged fiercely for more than two hours, completely destroying the main building. The hospital at that time accommodated about 400 patients, but fortunately no loss of life is reported, and all were taken to private hospitals in the city. The loss is estimated at 5,000,000 yen.

New Hospital for Municipal Employees

The municipal authorities of Tokyo have announced that they have planned to establish a large hospital for the municipal officials and their families, who are said to number about 90,000. Some of the public offices have had hospitals for their workers for several years under the system of health benefit insurance. The new hospital plan is based on the following statistical facts. In 1932 the average medical expense a month of each official's family was about 5 yen, the whole domestic expenses of each family being 91 yen and 47 sen on an average. Consequently 22,000 families have paid more than a million yen every month as their medical expenses. The estimated number

of outpatients is 730 and the inpatients 157 a day. The estimated income is about 272,000 yen a year. There are already in Tokyo seven hospitals established by different public bodies, and when this one is complete other public bodies are expected to build hospitals. The police, the school teachers, the street car workers, the government railway and the naval officers and men have their own hospitals.

Encephalitis Less Prevalent

Only 272 cases of encephalitis were reported in 1934, which is a remarkable decrease compared with the last few years. Following are figures showing the cases reported in the last eight years.

Year	No. of Cases	Deaths	Percentage
1927	988	697	70.55
1928	70	60	71.43
1929	2,043	1,163	56.90
1930	499	389	72.14
1931	129	97	75.19
1932	689	391	56.46
1933	791	510	64.48
1934	272	104	61.65

Koch Memorial Lecture

The twenty-first Koch Memorial Lecture was given, Dec. 11, 1934, in Tokyo, by Dr. S. Tsurumi, a member of the health section of the League of Nations, on medicine and international friendship. He spoke about the Franco-Japanese medical commission that was organized last June while he was in Paris. The commission will undertake to provide mutual facilities for work, also conveniences to those who travel on medical inspection tours, and the exchange of professors between universities. After Dr. Tsurumi's address, Dr. S. Yoshiue, professor at the military medical school, lectured on poison gas and air defense in future wars.

The Number of Physicians

According to the sanitary bureau of the home office, the number of medical men in 1934 in the country was 52,792, while in 1933 it was 50,069. The increase is 2,723 over 1933, but when compared with 1932 the increase is 4,692. Thus there will be a flood of physicians in the near future, if it is not controlled. There are 771 practitioners to each 10,000 of population on an average. In cities there are 13.24, and in villages there are 4.78. The number of dentists is 17,984, while in the previous year it was 17,164, the increase being 840. There are 56,590 midwives of whom there were 54,655 in the previous year. The number of pharmacists is 21,807, which shows an increase of 1,332, compared with 1933. The number of nurses is 96,020, while there were 89,686 in 1933. These figures are for the close of the year 1934.

The Japan Medical Association to be Expanded

The Japan Medical Association, the only medical body in this country, heretofore has excluded medical men in new territory such as Taiwan (Formosa), Chosen (Korea) and Karafuto (Sakhalin). A movement is being made now to expand the association to include all Japanese physicians in this country, no matter where they may live. When the plan is realized the number of members will be greatly increased. It is expected that the expansion will take place in the near future.

Abolishment of State Examination in Korea

An important change was made concerning the state examination for practitioners in Korea. This examination was a special one that authorized those who passed to practice medicine in Korea only. As it was rather easy to pass, many went to Korea to take the examination. The governor general of Korea has declared that this examination would be abolished in and after 1941, for the reason that there are now so many medical colleges, dental schools and pharmacy colleges, to say nothing of the Keijyo Imperial University Medical Department.

Marriages

WILLIAM WORTHINGTON SANUELL to Mrs Addie Keating Bradford, both of Dallas, Texas, January 22

WILBURN C YOUNG, Canal Point, Fla to Mrs Evelyn Logsdon of West Palm Beach, Dec. 31, 1934

THEODORE R DAVIES, Barboursville, Ky to Miss Elizabeth Ragsdale at Cleveland, Tenn., Dec 9 1934

BADIE T CLARK, Rocky Mount, N C, to Miss Margaret Page Smith of Atlanta, Ga, January 19

JOE IVEY TURBERVILLE, Century, Fla to Miss Ellen Virginia Burns of Frisco City, Ala, January 25

JOHN G ROBERTSON, Tofino, B C, to Miss Marguerite Heisler of Vancouver, Nov 29 1934

WARREN S BALDWIN to Mrs Ada Simpson Smollen both of Birmingham, Ala, February 2

EDWARD A THORNE, Scottsboro, Ala, to Miss Ruth O Hare of Birmingham, January 12

VERNON B WOOD to Miss Lucille Lintner, both of Ironton, Ohio, Dec 31, 1934

OTT CASEY, Clinton Ind, to Mrs Rosa Storm of Chicago, Dec 26 1934

Deaths

Morie Frederick Weymann of Los Angeles, Washington University School of Medicine, St Louis, 1922 clinical professor of surgery (ophthalmology) at the University of Southern California School of Medicine, member of the American Academy of Ophthalmology and Oto-Laryngology, the American Ophthalmological Society and the Pacific Coast Ophthalmological Society, on the staff of St Vincent's Hospital associate editor of the *American Journal of Ophthalmology*, aged 35, died, January 13 of poison self administered.

Kate Wylie Baldwin of Philadelphia Woman's Medical College of Pennsylvania, Philadelphia 1890 member of the American Academy of Ophthalmology and Oto-Laryngology, formerly demonstrator, clinical instructor and instructor in surgery and adjunct professor of surgery at her alma mater for many years on the staffs of the Woman's and Children's hospitals, fellow of the American College of Surgeons died, January 18, at Lawrenceville

Henry Adsit, Buffalo Johns Hopkins University School of Medicine, Baltimore, 1906 fellow of the American College of Surgeons served during the World War at various times on the staffs of the State Institute for the Study of Malignant Disease, Children's Hospital and the Buffalo City Hospital aged 55 died suddenly, February 7, of acute dilatation of the heart while playing hand ball

Charles F W Wilhelm of East St Louis Ill St Louis Medical College, 1880 past president and secretary of St Clair County Medical Society fellow of the American College of Surgeons, formerly health officer of East St Louis at various times chief of staff of the Christian Welfare Hospital and St Mary's Hospital, aged 76, died, January 28, of cerebral hemorrhage

Otho Boyd Will, Peoria Ill Rush Medical College, Chicago 1869 member of the House of Delegates of the American Medical Association in 1902 and in 1906 member and past president of the Illinois State Medical Society one of the founders and on the staff of the Proctor Hospital aged 88 died, January 28 of chronic nephritis and cerebral arteriosclerosis

Hiram Elmore Zerner, New Castle, Pa Western Pennsylvania Medical College, Pittsburgh, 1899 fellow of the American College of Surgeons past president of the Lawrence County Medical Society, aged 62, on the staffs of the New Castle Hospital and the Jameson Memorial Hospital, where he died, January 14, following a prostatic operation

Michael Earl Brennan of East St Louis, Ill St Louis University School of Medicine, 1921 past president of St. Clair County Medical Society for sixteen years bacteriologist for the city health department aged 40 on the staff of St. Mary's Hospital where he died, January 31, of carcinoma of the larynx

William Curtis Wolverton of Linton N D, State University of Iowa College of Medicine, Iowa City 1905 fellow

of the American College of Surgeons, formerly member of the school board, owner and medical superintendent of a hospital bearing his name, aged 55, died, January 11, of heart disease

Alexander Balfour Jeffrey of Topeka Kan., Northwestern University Medical School, Chicago 1906, served during the World War, medical director of the National Reserve Life Insurance Company, aged 55, died, January 25, in Christ's Hospital, of pneumonia, following an operation for appendicitis

Alton LeRoy Smith, Woodward Iowa State University of Iowa College of Medicine, Iowa City, 1931, member of the Iowa State Medical Society on the staff of the Hospital for Epileptics and School for Feeble-minded aged 29, died January 21, in the University Hospital Iowa City, of meningitis

William K Turner, Seattle, Hospital College of Medicine, Louisville, Ky, 1895 member of the Washington State Medical Association, aged 64, on the visiting staff of the Swedish Hospital, where he died, January 12, of fracture of neck of the right femur, pituitary tumor and bronchopneumonia.

John M Kennedy, Knoxville, Tenn, University of Pennsylvania Department of Medicine, Philadelphia, 1870 member of the Tennessee State Medical Association, Confederate veteran, aged 88 on the staff of the Fort Sanders Hospital, where he died January 24, of intestinal obstruction.

Robert W Lehigh, Necedah, Wis, American College of Medicine and Surgery Chicago 1905, member of the State Medical Society of Wisconsin, aged 59, died, January 12 in the Mauston (Wis) Hospital of pneumonia, as the result of injuries received when struck by an ambulance.

Charles Augustus Knowles, Boston Tufts College Medical School, Boston, 1927, member of the Massachusetts Medical Society, on the visiting staffs of the Boston City Hospital, St Elizabeth's Hospital and the Cambridge (Mass) Hospital, aged 30 died, January 31, of pneumonia

Harry Edward Knight, Detroit, Chicago College of Medicine and Surgery, 1917 member of the Michigan State Medical Society, on the courtesy staff of the Providence Hospital and on the staff of Grace Hospital, aged 43 was killed, January 27, in an automobile accident

Charles Melvin Wallace, Winterset, Iowa Ensworth Medical College, St. Joseph 1908 member of the Iowa State Medical Society past president of the Madison County Medical Society on the staff of the Winterset Hospital, aged 64, died, January 10 of heart disease

Julius Tyndale Westerman of Miami, Fla, New York University Medical College, 1896, Cornell University Medical College New York, 1899 served during the World War on the staff of the Miami City Hospital, aged 63, died, January 27, in Tampa, of thrombosis

Frank Anthony Laurer of Syracuse, N Y, Syracuse University College of Medicine, 1921 served during the World War on the staffs of the Syracuse Memorial Hospital and St Joseph Hospital, aged 39, died, January 29, of broncho pneumonia and meningitis

David Ulysses Sherman, Springfield, Mo Beaumont Hospital Medical College, St Louis 1898, member of the Missouri State Medical Association aged 63 on the staff of St. John's Hospital where he died, January 22, of cerebral sclerosis following fracture of the leg

Joseph Martin Thompson, Tahlequah Okla, Missouri Medical College St Louis, 1889, member of the Oklahoma State Medical Association, aged 69 died, January 2 in the Veterans' Administration Facility, Muskogee, of pulmonary tuberculosis

James Edwin Simpson, Salem, Mass, Harvard University Medical School, Boston 1891, member of the Massachusetts Medical Society on the staff of the Salem Hospital, aged 65, died, January 19, of probable carcinoma of the cecum

Henry Mortimer Sanger, Providence, R I Hahnemann Medical College and Hospital of Philadelphia, 1892 member of the staff and past president of the Homeopathic Hospital aged 64 died suddenly, Dec 26, 1934 of coronary occlusion

Richard Douglas Dill, Arvada Colo St Louis College of Physicians and Surgeons 1909 member of the Colorado State Medical Society aged 50 died January 18 in St. Joseph's Hospital, Denver, of septicemia following hypodermic injection.

Oscar Emery Morehouse, Upper Keswick, N B, Canada, McGill University Faculty of Medicine, Montreal, Que., 1889 for nine years district medical health officer aged 77, died January 1 in the Victoria Public Hospital Fredericton.

Casper Stock, New York, College of Physicians and Surgeons, Medical Department of Columbia College, New York 1894, member of the Medical Society of the State of New York, aged 63, died, January 15, in the Lenox Hill Hospital

Noble Van Zant, Monmouth, Ill., College of Physicians and Surgeons of Chicago, School of Medicine of the University of Illinois, 1906, on the staff of St Mary's Hospital, Kankakee, aged 52, died, January 17, of coronary occlusion

William Boone McClure, Towanda, Kan. University of Nashville (Tenn.) Medical Department, 1899, member of the Kansas Medical Society, on the staff of the Allen Memorial Hospital, El Dorado, aged 60, died in January

John Daniel Smetzer Young Graccham Md College of Physicians and Surgeons, Baltimore, 1887 aged 72 died recently, in the Emergency Hospital, Washington, D C following an operation for removal of the prostate

Frank Arthur Will Des Moines, Iowa State University of Iowa College of Medicine, Iowa City, 1909 served with the British Army during the World War, aged 48 died January 21, of heart disease and hypertension

John Perrill Hetherington, Logansport, Ind Eclectic Medical Institute, Cincinnati, 1890, formerly member of the city council and county coroner, aged 65 died January 26, in Miami, Fla., as the result of x-ray burns

Jacob W B Wellcome Jr, Sleepy Eye Minn., St Louis College of Physicians and Surgeons, 1890 member of the Minnesota State Medical Association aged 67 died January 3, of cerebral hemorrhage and hypertension

INITIAL INFECTION WITH TUBERCULOSIS AND SUBSEQUENT LESIONS

To the Editor—In their paper on the effect of initial tuberculous infection on subsequent tuberculous lesions (*THE JOURNAL*, Nov 17, 1934 p 1530) Myers and Harrington state that the chances of positive and negative reactors to tuberculin of developing clinical disease in the next few years are five or ten to one in favor of the positive group" and based on these statements they draw their conclusions as to the importance of allergy

But the comparison which the authors make between the morbidity in these two groups must be said not to permit any conclusions as to the risk of contracting tuberculous disease, as the two groups cannot be compared. A direct comparison would be possible only if all the individuals in the negative group were exposed to tuberculous infection during the period of observation. Tuberculin negative individuals who are not exposed to infection cannot be expected to develop clinical tuberculosis. This is a fact that has been neglected by many investigators and latest by Myers and Harrington. The importance of a correct statistical treatment of these matters was first stated by R. Hoyer Dahl (*Tidsskr f d norsk Lægeforening* 1933, No 3), who showed that, if one shall calculate correctly the percentage incidence of clinical tuberculosis in a group of formerly negative reacting individuals, one must know, or be able to calculate, how many of the negative individuals have turned positive, that is, been infected, during the period of observation. Further corrections must be made if the comparison is to be of statistical value. If the period of observation is ten years, all the positive reacting individuals can be reckoned as having been observed during ten years but of the formerly negative individuals a certain number are infected every year, corresponding to a certain curve. If this curve is linear the negative individuals can be reckoned only as having been observed during five years.

In his well known investigations of the nurses of Ullevaal Hospital, Oslo, Dr J Heimbeck has compared the incidence of clinical tuberculosis in a group of negative and a group of positive reacting nurses. And here the groups can be directly compared, as Dr Heimbeck has shown that all the negative reacting nurses are infected during the period of observation (three years). He finds for the three years 48 per cent clinical tuberculosis in the group of positive reacting nurses, against 34.6 per cent in the negative group (including milder forms of tuberculous disease, as erythema nodosum).

For medical students who during their work in the hospital are exposed to a risk of infection that is considerably smaller than that of the nurses but greater than that of the total population, O Scheel has found an incidence of clinical tuberculosis of 1.47 per cent in the group of formerly positive reacting individuals and 4.31 per cent in the group of negative reacting. The real difference will here be still greater, as a part of the negative reacting students are not infected during the period of observation.

Finally I will mention an example showing the difference between the wrong and the correct method of comparison. In a material consisting of 4,800 children from 4 to 16 years of age tested with the Pirquet reaction in 1930, I found in the following two years fifty-nine cases of clinical tuberculosis (*Beitr z Klin d Tuberk* 83 402 [Sept 23] 1933). If these cases are calculated directly on the negative and positive group, in the same manner as that of Myers and Harrington, the yearly incidence of clinical tuberculosis will be 31 per thousand

in the positive group, against 7 per thousand in the negative group. But on calculating, from the incidence of reactions to the Pirquet test in 1930 in the different ages, how many of the negative reacting can be expected to be infected during this time, and then calculating the morbidity in the manner of Høyer Dahl, I find an incidence of clinical tuberculosis of 80 per thousand in the negative group, that is, more than ten times as high as in the positive group.

Another circumstance that speaks directly against the importance of strong allergy for the development of tuberculous disease is that, with the erythema nodosum patients, almost in every case one finds a very strong Pirquet reaction, most frequently vesicular, and still the chance for these patients of developing clinical tuberculosis seems to be rather small. Investigations (Ustvedt H J and Johannessen, A S *Acta med Scandinav* 80 263 [no 3] 1933) have shown a morbidity of 10.3 per cent the first year, and for the following years, up to the tenth, from 3 to 0 per cent, which is hardly higher than in the total population.

HANS JACOB USTVEDT, M.D.,
Ullevaal Hospital Oslo

LEGAL AND MEDICAL RELATIONSHIPS

To the Editor—In THE JOURNAL February 2, there are several news items of interest which should not pass without comment.

On page 424, under Medicolegal, a case is reported from the California courts wherein the manager of a drug store was fined and the judgment sustained in the appellate court, because he permitted a nonregistered helper to sell hydrogen peroxide. I presume any one could sell Crazy Water Crystals with impunity. This report is consistent with the 'high grade' medical practice act of California and from an intelligent standpoint is on a par with the 'monkey law' of Tennessee.

Under Medical News page 407, H 73 Missouri proposes to forbid the sale or other distribution of acetylsalicylic acid, carbolic acid or iodine except on the prescription of a licensed physician, dentist or veterinarian. This smacks of the time when whisky was obtained on doctors' prescriptions and will act only as a boomerang to the medical profession. When the people need such protection it is quite dangerous to be alive. Such laws and such administration are what make it impossible to procure respectable food and drug legislation.

H A MCGUIGAN, M.D., Chicago

IODINE AND IODINE ACNE

To the Editor—In a case report on the treatment of chronic vaginitis with phenylmercuric nitrate (THE JOURNAL, January 19, p 212) the patient described by Dr Frederick W Hitchings developed an indurated pustular acne of the face and neck after treatment was instituted for the vaginitis. Listed with the drugs used in the treatment of the vaginitis was 2 per cent tincture of iodine and 10 per cent tincture of iodine, which were applied to the vaginal mucosa and the cervical canal respectively.

Iodine may be absorbed in sufficient quantity through the vaginal mucosa to produce iodide acne. I observed one patient in whom iodide acne resulted from the use on three different occasions of douches of compound solution of iodine. On each occasion the iodide acne disappeared in three weeks following the withdrawal of the solution, only to reappear within one week on resumption of its use. It is a very probable explanation of the acneform eruption that appeared during the treatment of Hitchings' patient.

This possibility was not mentioned in the case report. The specious conclusion was drawn that the acne was connected

with the vaginitis present. Both were attributed to a staphylococcus. It seems more reasonable to accept the acne in this case as an iodide acne than to accept the hypothesis that it was due primarily to the staphylococcus.

ARTHUR G SCHUCH, M.D., Dallas, Texas

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted on request.

TRAIN SICKNESS AND POSITION OF HEAD IN SLEEPING ON TRAINS

To the Editor—Most persons in riding on a train prefer to sit facing forward. But in sleeping in a berth the head is by choice placed toward the front of the train. In ambulances it is also routine for the head of the patient to be at the front of the conveyance. Is there a rational physiologic explanation for having the head in the direction of motion when horizontal either for sleep or when awake? This brings to mind the practice of Charles Dickens and other Victorian notables of carrying a compass and having the hotel bed placed with the head to the north. Having the head forward when sleeping on a moving conveyance however is so universal that I wonder if there is a reason other than the dead hand of custom for it.

DONALD A LAIRD, PH.D., Hamilton N.Y.

ANSWER—Man is used to the type of visual change or sensation produced by approaching an object, since his eyes are directed forward. In consequence, many people are affected by dizziness, nausea and vomiting, with the eyes open in a fast moving conveyance such as a train. Usually these disturbances are not produced if the eyes are closed when riding backward or if the vision is fixed on the objects in the train itself. But there is no evidence, rational or experimental, indicating that a person sleeps better or more comfortably in a moving conveyance when the head is directed toward the direction of motion. And the same answer applies to the notion of sleeping better or more restfully with the head directed toward the north. The only possible influence on the body that could be affected by the position of the head in a moving conveyance would be the action of gravity on the blood flow or tension on the viscera but most of the traveling speeds are insufficient to have any appreciable effect in this regard. It is well known that in many European countries the arrangements of the beds are transverse to the motion rather than in the line of motion, as it is in the 'bedroom' cars on the more progressive railways of the country. It is true that modern technique in the studies of sleep have reached a degree of perfection that permits accurate quantitative information of the restfulness or depth of sleep under any or all conditions. These have not yet been applied to the person sleeping in a moving conveyance.

For the present therefore, it appears that placing the head in the direction of motion on a train, ambulance or even ships at sea is purely a habit or tradition, and the same applies to the view that sleep is more profound with the head pointing north. Of course in persons in the habit of retiring with the head in a fixed direction and convinced by tradition that this is the best way to obtain restful sleep, that belief will set up worry which interferes with the prompt going to sleep or the depth of sleep when the position of the body in space is changed.

BLOOD SUGAR

To the Editor—How long after blood is taken and oxalated may it be allowed to stand before analyzing for blood sugar? If blood is taken in the morning at Somerset Ky it does not leave town until late afternoon and could not be delivered to any laboratory in time for analysis before the following morning. Would examination of a specimen that had stood for this length of time give accurate or reliable results?

M C SPRADLIN, M.D., Somerset Ky

ANSWER—Blood sugar determinations should be made immediately after the blood sample has been taken, as the dextrose rapidly disappears by glycolysis. Efficient refrigeration retards this glycolysis but does not prevent it. When the analysis cannot be made immediately the proteins of the blood should be precipitated and the filtrate, to which is added a few drops of toluene, placed in the refrigerator. This filtrate will give accurate readings for twenty-four hours after precipitation.

The blood filtrate is produced as follows: To 2 cc. of blood obtained in a test tube containing a small amount of powdered

potassium oxalate (2 mg per cubic centimeter of blood) to prevent clotting, 14 cc of distilled water is added and the mixture is allowed to stand until laked. Then 2 cc of 10 per cent sodium tungstate is added and after mixing, one adds 2 cc of two thirds normal sulphuric acid slowly while shaking. The flask is corked and shaken vigorously. Filtering is done through a small filter paper. The clear filtrate is then used for the colorimetric sugar determination. Two cubic centimeters of filtrate corresponds to 0.2 cc of blood.

A blood specimen standing four hours at room temperature shows a marked reduction of the blood sugar value, and in twenty four hours the blood sugar may be reduced to one half or less. One drop of a saturated solution of potassium fluoride added to 5 cc of blood in place of oxalate will prevent coagulation and also prevent the change in sugar content. This last procedure would be best for blood to be sent to a laboratory.

TREATMENT OF SYPHILIS

To the Editor—A man aged 40 first seen by me in May 1931 had bronchopneumonia complicated by kidney disease. The urine at that time contained four plus albumin and many white and red blood cells. The patient was edematous. The nonprotein nitrogen was 80. He recovered from the pneumonia and the urine gradually improved. One month later the patient called my attention to a lesion on the penis which he said was getting larger and he gave me a positive history of syphilis which had been treated. The Wassermann and Kahn reactions were both four plus. From his preceding physician I obtained the following report as to his treatment: he stated that he did not have sexual exposure during the past six months. Prior to July 1929 he had had forty six injections of neoarsphenamine totaling 442 Gm. and 54 grains (3.5 Gm.) of mercuric salicylate; the number of doses was not stated. On this date the Wassermann reaction was negative. From July 1929 to July 1930 he had seven injections of neoarsphenamine totaling 463 Gm. and seven injections of bismuth tartrate each 2 cc. Repeated Wassermann reactions were negative. No further treatment was given until June 1933. From the latter date he has received continuous treatment to date except for three months when he was away from my locality. I started treatment with mercury rubs and iodides for two weeks and then started neoarsphenamine giving him eight doses and then from ten to twelve doses of sodium bismuth thioglycollate or sodium bismuth iodides as follows: neoarsphenamine twenty two injections 12.9 Gm. sodium bismuth thioglycollate thirty injections 2 cc each; mercury rubs fifty four. Iodides have been given with the heavy metals. The urine has been normal during this time and the spinal fluid is normal. There are no symptoms of vascular involvement. Blood Wassermann reactions have been negative since the first series but Kahn reactions have been reported one plus two plus, and the last one three plus. Should the man have further treatment? Please omit name.

M D California

ANSWER—This query deals with a patient whose syphilitic infection is apparently entirely latent and who has had in all seventy seven injections of an arsphenamine product together with an appropriate associated amount of heavy metal, but whose Kahn test remains persistently positive. His infection was complicated by an apparently severe acute hemorrhagic nephritis from which he appears to have made a satisfactory recovery, although information regarding kidney function tests is not supplied.

Under these circumstances it seems undesirable for the patient to receive further treatment. On the basis of the study of the Cooperative Clinical Group the chance of subsequent progression or relapse is only about 1 in 20. This should be guarded against by yearly periodic general physical examinations with particular reference to the nervous system and the cardiovascular apparatus, and with quantitatively titered blood Wassermann tests done at intervals of every six months. Treatment need not be resumed unless there are clinical evidences of progress or unless a high titer Wassermann relapse appears.

TRAUMATISM AND METRORRHAGIA

To the Editor—I should appreciate it if you would be so kind as to give me the etiology of the bleeding in the following case as I am unable to find anywhere any relation between traumatism and metrorrhagia. The patient is 30 years of age and married. Her family and past history are negative. On the first of June she had a fall down a flight of stairs and shortly afterward complained of considerable pain in the abdomen and started to bleed from the vagina although her regular period was a week previous to that. Dilatation and curettage were done but the results were normal. She continues to have some bleeding. The uterus is of a normal size and a normal consistency. Please omit name.

M D Bound Brook N J

ANSWER—It is difficult to offer a satisfactory explanation in this case because it is rare for trauma to be followed by bleeding from the vagina except when the injury involves the vagina. In the realm of probabilities rupture of a corpus luteum or corpus luteum cyst of one of the ovaries must be

considered, because rupture of these portions of the ovary is often followed by uterine bleeding. In spite of the fact that the patient had a presumably normal menstrual period it is possible that the patient had an ectopic pregnancy which was ruptured by the fall. In such a case the endometrium would most likely show some decidual reaction. The severe pain in the abdomen could have been associated with either rupture of a corpus luteum cyst or ectopic gestation. Direct injury to the uterus is rarely ever followed by bleeding from this organ.

NEUROLOGIC SYMPTOMS AFTER TRAUMA

To the Editor—A colleague of mine aged 49 5 feet 6 inches (168 cm) in height weighing 155 pounds (70 kg) received a head injury last December. He was unconscious for about fifteen minutes. I saw him about two hours later with a hematoma about the size of a hen's egg over the occiput. He was then dazed and complained of severe head ache. I administered a sedative and advised prolonged rest. After two days he went to his office to resume practice though still complaining of headache and vertigo. Despite advice to the contrary he tried to carry on in a limited way but he had to desist after five months. Frequent physical examinations and laboratory tests have so far failed to disclose any other cause for this disability. His major trouble at this date is loss of visual acuity and contracted visual fields (concentric) with no objective changes observable in the fundus of either eye. Neurologic tests are negative. Blood pressure readings have varied in the past three months from 140/95 to 175/120. His hypertension now seems to be stabilized at 165/110. He has lost about 10 pounds (4.5 kg) although having no gastro-intestinal disturbances and his appetite remains normal. His habits have always been good. Roentgenograms of the skull blood chemistry blood counts basal metabolism urinalyses and an electrocardiogram have not disclosed any information and the patient is much depressed. I should like to know whether it is possible for symptoms such as the marked asthenia vertigo and headaches to appear so late and to last so long and what your opinion is as to the ultimate outcome. Encephalography has been offered to the patient for the relief of the post traumatic headache but he is much more concerned about his visual disturbance and has not yet acceded to it. Kindly omit name. M D California

ANSWER—Three groups of facts must be available to form the basis for an opinion in a case of this kind and only two of them are given in the statement of the case. It is stated that the patient reacted to a head injury and that the reaction consisted in certain phenomena. In addition, it should be told with what the patient reacted in other words, more should be known about his person than is stated here, namely his age weight profession and good habits. It should be particularly stated whether or not he is of a sensitive or neurotic make up as a person of this kind is likely to show quite an array of functional symptoms even after a slight injury. One would also like to know whether any claim for damages is involved as even the most high minded and well meaning professional men may be subconsciously influenced if a claim exists. Though not looking for personal gain, they feel that it is their duty to their family and to the cause of justice that they be properly compensated. In view of the severity of the injury a certain amount of genuine concussion probably was sustained, and this may account largely for the headache and vertigo. The concentric narrowing of visual fields the depression and asthenia are most likely due to a traumatic neurosis.

MULTIPLE STILLBIRTHS

To the Editor—A woman now 27½ years of age married at the age of 23 gave birth at 25½ years to an eight months stillborn male fetus weighing 3 pounds (1360 Gm) having gained only 8 pounds (130138) during her pregnancy. Her antepartum period was marked by severe headaches and persistent vomiting during the first seven months. A very easy spontaneous delivery was preceded by only twenty minutes of severe labor pains. Her physician explained that the cord had snapped before delivery. At 27 she gave birth to a nine months stillborn male fetus weighing 4½ pounds (2040 Gm) having gained only 12 pounds (130142) during her pregnancy. This antepartum period was entirely without incident. The delivery was abnormal with five days of intermittent pains and about six hours of severe pains finally terminating in a forceps delivery. The same physician explained that the placenta had separated twelve hours before delivery. Have you any statistics as to the possibility of or the frequency of occurrence of breaking of the cord in utero? Is there any explanation for the small size of these fetuses and the lack of appreciable gain of weight in the mother? The caloric intake was quite sufficient in both pregnancies. The patient is anxious to have a live baby. What precautions or suggestions can you offer that would be of aid in satisfying this wish?

M D New York

ANSWER—There are no statistics of the frequency of spontaneous rupture of the cord in utero, but there are a few cases on record and none of them explain the cause of the brittleness of the cord. Sometimes the cord will break in a rapid delivery if it happens to be caught round the shoulders and is short in the first place.

There are many causes for stillbirths, and the facts given in this case are not sufficient on which to make a diagnosis or even a surmise. It would be necessary to know whether there

is any latent syphilis in either parent, whether the mother has chronic nephritis or diabetes or other general disturbance that could exert an influence on the fetus and its envelops. Further, a study must be made of the various deficiency diseases of the mother, avitaminosis or other metabolic disturbances. Finally, endocrine dysfunction has to be considered and here, of course, there is no end to possible theorizing.

As for future pregnancy, every possible general disturbance should be ruled out and the patient should be given the usual roborant and tonic regimen under consultation with an internist.

DEATHS FROM CARBON MONOXIDE

To the Editor—As I shall in the near future testify in a compensation court with regard to a death claim in which it is suggestive that death was caused by carbon monoxide poisoning following several hours work in the front chamber of a locomotive with an acetylene torch I would be grateful to you if you can give information on the following points: 1 Have you any facts or information about a catastrophe that occurred in Belgium a few years ago in which many people in a small town died after inhaling one form of poisonous gas? The importance of this is that these people died although the gas was drifting in the open air. This was reported at the time in the American newspapers. 2 Could a man after inhaling a considerable quantity of carbon monoxide gas walk unaided about 150 feet to a water fountain and then die at that point of this gas poisoning? Would the walk tend to revive him even though it was taken in a large engine room (a round house) where of course the air was not very good for the purpose intended—to get more oxygen? 3 Would the fact that this occurred on a very hot day with a high humidity increase his susceptibility to this gas and therefore make poisoning more easily possible under the circumstances? 4 To be killed by carbon monoxide poisoning is it absolutely necessary that one become unconscious and then die or is it possible for such an interval (question 2) of consciousness to occur and then death follow very soon afterward? This is the important point. This death occurred one year ago and no autopsy was done hence the litigation. Kindly omit my name if printed in THE JOURNAL. M D Pennsylvania

ANSWER—1 There is no reliable evidence on record that any of the deaths associated with the fog in Belgium resulted from poisoning by any form of gas drifting in the open air. This subject was fully discussed by the Belgian correspondent of THE JOURNAL in the issues for May 28 and Aug 6 1932.

2 It would seem to be most highly doubtful, to say the least, that a person after inhaling a fatal amount of carbon monoxide could walk 150 feet just before dying from the effects of the monoxide. Any form of physical work in an atmosphere containing carbon monoxide will tend to increase the rate of absorption of the monoxide.

3 It is not at all clear how heat and humidity can increase "susceptibility" to carbon monoxide.

4 The rule is that unconsciousness comes on before death in poisoning from carbon monoxide. Cases described in miners especially, of sudden death in mine explosions might be interpreted as an exception to this rule.

NEUROSYPHILIS

To the Editor—A woman aged 29 was first seen by her physician in 1928 because of a soreness about the genitalia. The blood Wassermann reaction was four plus. She was then given two courses of neoarsphenamine and an unknown number of intramuscular injections over a period of two years. At the end of this time her blood remaining four plus she was pronounced Wassermann fast and discharged. About a year and a half later she developed pains in her shin bones. Roentgenograms showed no periostitis. The blood Wassermann reaction was four plus. The reaction of the spinal fluid was four plus Wassermann two plus Pandey and it contained 16 cells per cubic millimeter. The gum mastic test was not done. For eight months following this she received irregular neoarsphenamine and iodobismutol injections. In January 1933 she came under my care. She complained particularly of a marked tremor of both hands which she stated had been progressing for the past five years. Complete physical examination revealed nothing of note. During the past year and a half I have given her ten injections of neoarsphenamine 0.45 Gm fifteen injections of tryparsamide 2 Gm eight injections of silver arsphenamine 0.15 Gm six intramuscular injections of mercuric succinimide and ten injections of iodobismutol. She has also had three courses of mercury rubs. Potassium iodide had to be discontinued as the patient tolerated it poorly. The results have not been encouraging. In April 1933 the Wassermann reaction was four plus. In November it was three plus. At this time the spinal fluid showed three plus and the gum mastic reading was 01100000. Sept 12 1934 her blood Wassermann reaction was two plus. Her tremor is as bad as ever. The patient had chorea in childhood. Does this play any part in the etiology of the tremor? I have considered paralysis agitans and multiple sclerosis but find no corroboration. What further treatment would you advise? Should malaria therapy be considered? If published please omit name. M D Ohio

ANSWER—The patient is young, she has had adequate antisyphilitic treatment and the Wassermann test remains fast. This is an ideal case for therapy with malaria. Six months and again a year later, serologic tests should be made.

The attack of chorea during childhood probably bears no relationship to the tremor now present. The tremor may be a manifestation of neurosyphilis or it may be unrelated. For symptomatic relief of the tremor, scopolamine may be tried, if this is effective, the result should be apparent within two or three days.

REMOVAL OF BECK'S PASTE FROM KIDNEY

To the Editor—Two months ago I operated on a man for a large stone in the first inch of the left ureter. All of the urine from the left kidney was discharged through a fistula in the wound for three weeks. I recommended to the patient the passage of a ureteral catheter to dislodge anything that might be preventing the urine escaping through the ureter. We procrastinated at the patient's request as he hated to submit to the procedure. Thinking that I might get the fistula to close, I injected Beck's bismuth paste into the fistula using about 6 drachms of the paste. I did not realize how small in caliber the fistula had become and did not think that that amount could possibly reach the pelvis of the kidney as the patient is a muscular man, weighing over 200 pounds but it did reach the kidney and calices with no stopping of the urine through the fistula. He then submitted to the catheter in the ureter with the result that the urine stopped coming through the fistula immediately and all of it now passes through the bladder. How can I get rid of that paste in the pelvis and calices of the kidney? Have you any suggestions? The patient is passing shreds of pus in the urine and has some inflammation of the urethra and trigon. If you have any suggestions to make anything that might dissolve that paste and avoid his having the kidney operated on it would surely be appreciated. Kindly omit name. M D Wisconsin.

ANSWER—If the amount of bismuth paste in the pelvis of the kidney is small one might try to dissolve it by injecting warm oil into the kidney pelvis through a ureteral catheter. A thin oil is to be preferred. Though one should not be unduly optimistic about the outcome of this procedure, it might be tried and controlled with repeated roentgen examinations. If this does not dissolve the oil and wash out the bismuth paste, it will be necessary to remove it through a pyelotomy incision.

PSORIASIS OF SCALP

To the Editor—I have a patient who has a severe case of psoriasis of the scalp. Treatment with an ointment containing ammoniated mercury 10 per cent and salicylic acid 3 per cent applied twice weekly followed by tar soap shampoos and stimulating tonics has been entirely unsuccessful. Can you recommend a better treatment? Please omit name. M D Michigan.

ANSWER—The treatment that is being used is not strong enough for psoriasis of the scalp. An ointment consisting of ammoniated mercury 12 Gm, wool fat 4 Gm and sufficient petrolatum to make 30 Gm is often efficacious. This should be rubbed into the individual patches every night. It may be left on for a day or two or it may be washed out every morning. The scalp should be washed twice a week, in any event. Any soap will do for this purpose. If this treatment fails, an ointment consisting of oil of cade 4 cc, salicylic acid 2 Gm, and ammoniated mercury 4 Gm may be tried. A 3 per cent chrysarobin ointment is effective but is likely to discolor the hair.

TREATMENT OF ULCER ON HEEL

To the Editor—A man aged 57 fell and fractured his right leg about a year ago. Following the break, the leg was put up in traction and as a result of neglect a pressure ulcer developed on the right heel. This was nearly an inch in diameter and extended to the periosteum but has gradually healed in from the sides with callus until now it is only a small sinus tract. The periosteum is covered by a thin layer of granulation tissue but this fails to increase to any appreciable extent. Can you suggest any form of treatment to help fill this in from the bottom or any surgical procedure to alleviate the existing sinus. Please omit name and address. M D Mass.

ANSWER—The os calcis should be irradiated. If there is no bony involvement, moist saline dressings should be applied with the patient in bed and the leg slightly elevated for one or two weeks or until the granulations are healthy, then skin grafting should be done.

RADIUM APPLICATIONS TO TONSILS

To the Editor—What is the current opinion about the use of radium in removing tonsils? The technique used is as follows: Two platinum needles are implanted in each tonsil and each needle contains 10 mg. of radium. The four needles are allowed to remain in place for two and one half hours and then the treatment is repeated every three weeks for a total of three or four such treatments. Please discuss. Kindly omit name. M D Missouri.

ANSWER—The consensus seems to be that the use of radium needles in the tonsils is not very good practice. Some years ago, attempts at removing tonsils with x-rays proved fallacious,

and while there was atrophy of the lymphoid tissue caused by the radiation and considerable diminution in the size of the tonsils themselves, they were not removed by this method but were later, in many instances, the seat of infection.

The implantation of platinum needles containing radium salt would, of course, produce destruction of certain portions of the tonsils, but there would be no assurance that they would be completely removed by this method.

In the last analysis, the only dependable method for complete elimination of the tonsils is their surgical enucleation.

HISTAMINE IN ARTHRITIS

To the Editor—I understand that histamine causes in most species a marked fall of blood pressure. Is it safe to treat a case of rheumatoid arthritis with this drug if the patient a woman aged 55 has a pressure of 110 systolic and 80 diastolic? **GOLDIE FINE MD Philadelphia**

ANSWER—Histamine by mouth has little or no physiologic action. For this reason it is given by the subcutaneous or the intravenous route. When given intravenously it is highly toxic. One milligram (one sixty-sixth grain) may cause nausea and as a consequence of this a marked fall in blood pressure. Hypotension might be considered a contraindication. In rheumatoid arthritis the joints involved are usually cold on account of vascular constriction. The use of various forms of heat to the joints will produce local vasodilatation without attendant danger.

VALUE OF ELECTROCARDIOGRAPHY

To the Editor—What if any serious cardiac diseases could exist without presenting any electrocardiographic evidence? Please omit name and address. **MD New York**

ANSWER—The electrocardiogram is of value in recording the various cardiac arrhythmias and myocardial damage involving the conduction system. Evidence is sometimes secured regarding disproportionate hypertrophy of the auricles or ventricles.

There are many anatomic lesions in which no electrocardiographic evidence can be obtained. For example, rheumatic valvular lesions without ventricular hypertrophy or myocardial damage, syphilitic aortitis, and early cases of hypertension. Coronary sclerosis with angina pectoris may present a normal electrocardiogram before thrombosis and myocardial infarction have occurred. There are probably some cases of coronary thrombosis of the smaller branches that show no electrocardiographic deformity.

TREATMENT OF BURNS

To the Editor—A man aged 72 was burned over a year ago and came under my care two months ago. I have tried all the usual treatments for burns but when I have it almost healed it breaks down. The burn covers nearly all the extensor surface of the thigh. If you have any suggestions I would appreciate them greatly. Kindly omit name. **MD Pennsylvania**

ANSWER—Large wounds of the type described are best treated by skin grafting. The field should be properly prepared for the reception of grafts and because the wound has frequently broken down it is probable that this would include excision of the superficial scar tissue after the granulating surface itself had been rendered clean and healthy. The most satisfactory type of grafts for the rapid covering over of these areas with skin are the small deep grafts or the Ollier-Thiersch grafts. The success of these procedures depends on experience in the grafting of skin and strict attention to technical details.

PREPARATION OF SCARLET FEVER TOXIN

To the Editor—Have you any information as to how the Dicks extract the toxins from streptococci? As I understand it there is a patent involved somehow but if the method of extracting endotoxins is known I would appreciate the information. I am working on the problem of a possible toxoid in the case of appendicitis and other infections as a preventive and for active therapeutic treatment. I have certain information of definite value but I am interested in the Dick method for the moment. **W A HUTTON MD Melrose Mass**

ANSWER—Scarlet fever toxin is a soluble toxin not an endotoxin. It is obtained by growing hemolytic streptococci specific to scarlet fever in a suitable medium. The preparation is rendered sterile so that it is available for use in human beings by killing the bacteria in the solution or removing them by filtration through porcelain filters of appropriate density. The resulting solution containing the toxin is then standardized by comparison with a standard toxin by means of skin tests.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILOLOGY *Written (Group B candidates)* The examination will be held in various cities throughout the country April 29. *Oral (Group A and Group B candidates)* New York June 10. Sec. Dr C Guy Lane 416 Marlborough St Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY *Written (Group B candidates)* The examination will be held in various cities of the United States and Canada March 23. *Final oral and clinical examination (Group A and Group B candidates)* Atlantic City N J June 10-11. Sec. Dr Paul Titus 1015 Highland Bldg Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY Philadelphia June 8 and New York June 10. *Application must be filed at least sixty days prior to date of examination* Sec. Dr William H Wilder 122 S Michigan Blvd Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY New York June 8. Sec. Dr W P Wherry 1500 Medical Arts Bldg Omaha.

AMERICAN BOARD OF PEDIATRICS Atlantic City N J June 10 and St Louis Nov. 19. Sec. Dr C A Aldrich 723 Elm St Winnetka Ill.

ARIZONA Basic Science Tucson March 19. Sec. Dr Robert L Nugent Science Hall University of Arizona Tucson.

Medical Phoenix April 23. Sec. Dr J H Patterson 826 Security Bldg Phoenix.

CALIFORNIA Reciprocity Los Angeles March 13. Sec. Dr Charles B Pinkham 420 State Office Building Sacramento.

COLORADO Denver April 3. Sec. Dr Wm Whitridge Williams 422 State Office Bldg Denver.

CONNECTICUT Regular Hartford March 12-13. *Endorsement* Hartford March 26. Sec. Dr Thomas P Murdock 147 W Main St Meriden. *Homoeopathic* March 12. Sec. Dr J H Evans 1488 Chapel St New Haven.

IDAHO Boise April 2. Commissioner of Law Enforcement Hon Emmitt Pfost 203 State House Boise.

ILLINOIS Chicago April 9-11. Superintendent of Registration Department of Registration and Education Mr Eugene R Schwartz Springfield.

MAINE Portland March 12-13. Sec. Board of Registration of Medicine Dr Adam P Leighton Jr 192 State St Portland.

MASSACHUSETTS Boston, March 12-14. Sec. Board of Registration in Medicine Dr Stephen Rushmore 144 State House, Boston.

MINNESOTA Basic Science Minneapolis April 23. Sec. Dr J Charney McKinley 126 Millard Hall University of Minnesota, Minneapolis. *Medical* Minneapolis April 16-18. Sec. Dr E J Engberg 350 St Peter St St Paul.

MONTANA Helena April 2. Sec. Dr S A Cooney 7 W 6th Ave Helena.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination June 24-26. Ex. Sec. Mr Everett S Elwood 225 S 15th St Philadelphia.

NEW HAMPSHIRE Concord March 14-15. Sec. Board of Registration in Medicine Dr Charles Duncan State House Concord.

NEW MEXICO Santa Fe April 8-9. Sec. Dr P G Cornish Jr 221 W Central Ave Albuquerque.

OKLAHOMA Oklahoma City March 12-13. Sec. Dr J M Byrum Mammoth Bldg Shawnee.

RHODE ISLAND Providence April 4-5. Dir. Public Health Commission Dr Lester A Round 319 State Office Bldg Providence.

WEST VIRGINIA Charleston March 18. State Health Commissioner Dr Arthur E McClure Charleston.

WISCONSIN Basic Science Madison March 16. Sec. Prof Robert N Bauer 3414 W Wisconsin Ave Milwaukee.

New York June Examination

Mr Herbert J Hamilton, chief, Professional Examinations Bureau reports the written examination held by the New York State Board of Medical Examiners in Albany, Buffalo, New York and Syracuse, June 25-28, 1934. The examination covered 9 subjects. Six hundred and thirty-one candidates were examined, 493 of whom passed and 138 failed. The following schools were represented:

School	PASSED	Year Grad	Number Passed
Stanford University School of Medicine	(1931)		1
University of Colorado School of Medicine	(1933 2)		2
Yale University School of Medicine	(1930 2)		2
George Washington Univ. School of Med	(1933 2) (1934 3)		5

Book Notices

American Medicine By Dr Henry E Sigerist the William H Welch Professor of the History of Medicine The Johns Hopkins University. Translated by Hildegard Nagel Cloth Price \$4 Pp 316 with 30 Illustrations New York W W Norton & Company Inc 1934

This volume, published originally in German, is now made available in an English translation. It begins with an introduction which explains that the volume results from a lecture tour by the author through the United States. Dr Sigerist is familiar with the history of medicine in this country and since 1932 has been professor of the history of medicine in Johns Hopkins University. He writes well and is concerned always with the giving of a complete picture rather than with the development of a reference work. He traces the growth of medicine in the United States from the opening up of the soil and colonial period through the development of the great industries. Then he discusses in brief biographies the pioneers who contributed notably to American medicine, concluding this section with the story of the rise of Sir William Osler. In his picture of medical education he emphasizes the significance of the development of Johns Hopkins University School of Medicine, giving most of the credit for the modern reform to Abraham Flexner and failing to appreciate, as do many others, the highly significant work of the Council on Medical Education and Hospitals. While the publicity associated with the investigations by Flexner may have been largely responsible for directing public attention to the situation it was chiefly the work of the Council and the publicity given to the matter in *THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION* that brought about the reform.

Dr Sigerist provides a most adequate outline of the whole procedure of examination and licensure. He discusses the relationship of physician to patient, describing the development of group practice and of the Mayo Clinic and urging health insurance as a rational solution of the problem of medical care for the multitude. He feels also that it would be wise to extend such systems to all the people rather than only to those in the lower income levels. He recognizes the responsibility that rests on the American Medical Association for the development of plans in the future and in this connection gives a brief outline of the development of the Association and of its headquarters office.

There are also brief discussions of the development of osteopathy and chiropractic as well as other one track systems of healing, including Christian science. The volume concludes with discussions of the hospitals and of preventive medicine, culminating with a consideration of American contributions to medical science and with a final tribute to Dr William H Welch. Dr Sigerist indicates that he proposes next to make a similar survey of medicine in Russia because the developments in Russia and in the United States he considers most significant for the practice of medicine in the future.

It is exceedingly interesting to have this point of view of the picture of American medicine. It is a point of view definitely biased by too limited contacts with strong minded people principally in the region of Baltimore and New York. The author apparently has been willing in many instances to accept, as authoritative statements founded more on prejudice than on fact. One might expect this of an occasional philosopher but it is not in accord with the methods of science or of sound history. One fears that the investigations of Dr Sigerist have been too superficial to warrant many of the conclusions which he rather lightly draws from his studies.

La tromboangeliia obliterante Por el Doctor Julio Diez jefe de servicio de cirugía del Hospital Alvear. Paper Pp 538 with 133 illustrations Buenos Aires El Ateneo 1934

This monograph on thrombo-angitis obliterans presents a fairly complete review of this interesting disease. It is divided into four sections: (1) general conceptions of vascular pathology, (2) anatomic and clinical study of thrombo-angitis obliterans, (3) sympathetic ganglionectomy—its history, the basic principles underlying it, and its application to the treatment of thrombo-angitis obliterans, (4) other surgical methods of treating thrombo-angitis obliterans. There is an appendix containing brief clinical histories of 138 patients on whom ganglionectomy had been performed. Since some were operated on two or three times, there were 150 observations. The illustrations add greatly to the clarity of the work.

While much of the material is a review of the extensive literature, some original observations on pathology and the physiologic effects of vasomotor paralysis are presented. In 300 personal observations Diez has never seen an instance of thrombo-angitis obliterans in a nonsmoker or in a woman. He is of the opinion that the initial lesion is a stenosing arteriolitis and that this is the same lesion which exists in Raynaud's disease. Diez believes that Raynaud's disease in the female is equivalent to thrombo-angitis obliterans in the male and that the essential difference lies in the fact that Raynaud's disease does not progress and that thrombo-angitis obliterans does.

A large section of the monograph is devoted to a discussion of the value of ganglionectomy in the treatment of thrombo-angitis obliterans. Since Diez was the first to perform ganglionectomy in the treatment of this disease and has consistently advocated this procedure for the last ten years, the record of his experience and his conclusions as to its value are of interest. He is enthusiastic about the good results and feels that it is the method of choice. The freedom from recurrence after ganglionectomy in ninety-two patients (only forty-two of whom have been observed more than two years) is stressed as evidence of the value of this operation. The statement is made that when all patients have a ganglionectomy performed early in the disease, mutilating amputations will no longer be necessary. Yet the author admits that even in ganglionectomized patients the continued use of tobacco results in relapses and amputations. It is difficult to reconcile these two statements. As a matter of fact, one American surgeon has observed 266 patients who have had no ganglionectomy and who have continued in excellent condition free from relapse from two to ten years, merely by avoiding the use of tobacco. Diez states that he is not in accord with surgeons who delay ganglionectomy when vasomotor tests show no elevation of temperature. He recommends the operation in all cases of thrombo-angitis obliterans, both early and late, except in the hyperacute forms. He is convinced that prophylactic ganglionectomy is justifiable. He states that the operation results in immediate and complete relief of pain in all cases, marked improvement in the healing of ulcers and gradual improvement in the intermittent claudication. Until January 1933 he performed the operation by the abdominal route with general or spinal anesthesia. He is convinced that several of the deaths in the early cases were due

to this technic, and he now employs local anesthesia and operates by the lumbar route. Seven immediate operative deaths and five later deaths occurred in the 119 cases of his first series. In the last twenty-one cases in which local anesthesia was used there were no deaths. Diez reports that the operation was unsuccessful in 21.86 per cent of cases, which is almost exactly the percentage of failures reported in 1934 by Brown of the Mayo Clinic.

Diez's enthusiasm for ganglionectomy as the choice of treatment in all patients with thrombo angitis obliterans is not reflected in this country, where the tendency has been to limit its use to particularly favorable cases. His valuable report will stimulate further interest in the operation and will aid in establishing the correct indications for its use.

The Vitamin B Requirement of Man. By George R. Cowgill, Ph.D. Associate Professor of Physiological Chemistry in Yale University. Published for the Institute of Human Relations. Cloth. Price \$4. Pp. 261 with 16 illustrations. New Haven: Yale University Press, 1934.

This monograph presents results of research designed to determine indirectly the human requirement for vitamin B. The author reasoned that, if some common relationship should be found to hold for quantitative data derived from several animal species, there would be some justification for believing that the same relationship holds for human beings. Therefore measurements were made of the amounts of a given vitamin B concentrate required by different sized mice, rats, pigeons and dogs. From the several groups of data thus obtained, a mathematical relationship common to all was discovered. The derived formula suggests that body weight, total metabolism or calories and the maximum normal weight of the species are the three important variables determining vitamin B requirement. Experiments with pigeons and dogs confirmed the formula.

From the animal data a formula applicable to man was derived. This was tested by study of the vitamin B content of numerous human dietaries (a) that were known to have been used by persons who developed beriberi, and (b) that were not associated with the appearance of this disease. The amounts of vitamin estimated in the various diets were compared with requirements of the individuals subsisting on them in order to determine their adequacy as predicted by the formula. The results of such study were also compared with the incidence of beriberi in the groups studied. An excellent agreement was obtained between predictions based on the formula and facts of the presence or absence of beriberi. Clinical implications of this research explain the presence of beriberi in various localities about the world and indicate possible shortage of vitamin B in North America and other countries where manifest beriberi is rare.

The material of this monograph will serve as a basis for future research of beriberi and of vitamin B needs of human beings for optimal nutrition. This excellent reference work will be especially useful to vitamin investigators and those concerned with public health. A few of the chapters are named to indicate the character of the subjects covered: general discussion of beriberi, animal experiments—general methods, tests with the pigeon, the dog, the white rat and the mouse, the amount of vitamin B present in different foods, the vitamin B content of diets not associated with beriberi and vitamin B in relation to other clinical conditions. A comprehensive bibliography is included.

Proceedings of the National Conference of Social Work [Formerly National Conference of Charities and Correction] at the Sixty First Annual Session Held in Kansas City, Missouri, May 20-26, 1934. Permanent Headquarters: 82 North High Street, Columbus, Ohio. Published for the National Conference of Social Work. Cloth. Price \$3. Pp. 621 with illustrations. Chicago: University of Chicago Press, 1934.

Compared with volumes reporting the proceedings of previous years, the most striking contrast is the change from discussions of technic to programs of social reform. Social insurance is a frequent subject and health insurance is urged by numerous speakers. John A. Kingsbury, I. M. Rubnow and Kendall Emerson, M.D., present extended arguments in favor, while many others urge such insurance incidentally to general relief programs. The papers presented cover practically all phases of activity of social workers and constitute the latest and most authoritative presentation of their attitude on current problems.

Les lavages de plèvre. Leur emploi dans le traitement des épanchements pleuraux tuberculeux. Par le Dr. Pierre Weiller, médecin assistant au centre de triage antituberculeux de l'Hôpital Beaujon. Préface de Michel Léon Kindberg, médecin des hôpitaux de Paris. Paper. Price 96 francs. Pp. 131 with 23 illustrations. Paris: Masson & Cie, 1934.

Many a successful artificial pneumothorax has come to grief with the development of an empyema. This phrase is not simply a form with which to impress and remind the student of one of the common complications of artificial pneumothorax but sad to say, a truism. Many methods of combating this complication have been developed and described, none of them always successful. Lavage of the pleura is one of these methods and when well carried out is effective in a fair percentage of cases. The technic is simple. Pierre Weiller, who with F. L. de Muralto has had a long experience with collapse treatment for pulmonary tuberculosis, describes in detail his methods of pleural lavage. In this monograph the indications for treatment and technic and the possible incidents during the treatment are well outlined. The average American physician will be able to find most of the important points regarding lavage theory in general in more readily available English works. For the phthisisist, however, and especially for one who likes to trace things to their source, this short, well written, concise monograph will be of great interest.

American Encyclopedia of Sex. By Adolph F. Nemoetter, B.S., A.B., M.A. Special Adviser on Sexual Anthropology to the American Anthropological Society. Including a Dictionary of Sexology and Erotology, a Vocabulary of Sex Slang and Americanisms, a Miscellany of Erotic Curiosities, a Lexicon of Medico-Sexological Expressions, a Reference Library of Scientific Sex Works, a Collection of Erotic Essays and Articles, a Glossary of Foreign Sex Terms, a Manual of Noted Names in Protophology, an Frottecon of Amatory Practices in America, a Compilation of Sexual Allusions in History and Literature. Cloth. Price \$5. Pp. 277. New York: The Panurge Press, 1935.

This is another of the sex books planned primarily to sell to those whose interest in sexual matters is above the average. The volume contains a considerable number of words in the sex field but fails to include most of the slang terms commonly used for the sex organs, the sex activities and the sex perversions. It is, however, sufficiently up to date to include a good definition of a fan dance. It fails also in the definition of such words as are particularly common among the Negroes in the United States in their discussions of sexual topics.

Five Hundred Delinquent Women. By Sheldon and Eleanor T. Glueck. With an Introduction by Roscoe Pound. Cloth. Price \$5. Pp. 539. New York: Alfred A. Knopf, 1934.

This book continues the series of researches made by these authors concerning delinquency in its various aspects. Previously they have studied male reformatory graduates and juvenile delinquents. The present book treats of female offenders, and the same technic is used that proved so successful before. Before the Gluecks made these reports there was no real knowledge extant to give one an idea of the efficiency of penal institutions. The number of crimes committed by recidivists was fairly good evidence that something was wrong but intense study and analysis of the situation were necessary before the success or failure of present methods could be fairly seen. In the present book five hundred women are studied. A vast amount of material covering the inmates' backgrounds before commitment to the institution, her institutional record and her behavior after discharge has been analyzed. Since the information is gained from only one institution (the Massachusetts Reformatory for Women), the conclusions drawn are possibly somewhat fallacious, for the Massachusetts reformatory where the study was made seems to obtain better results than many in other states. So much information is packed into this volume that it is almost impossible to give an adequate idea of the conclusions drawn. For example, there are almost 150 pages of tabulated results without discussions, which gives some idea of the work presented. This tabulation and a discussion of methods used and a list of definitions occupies about the last third of the book, and, although this part contains supposedly only the appendixes, it would be read with profit before one studies the body of the book. The first third of the book proper would be the most interesting part to the chance reader. It describes the family background of the subject, a presentation of the reformatory picture, and contains two chapters entitled "A Gallery of Women" which give a graphic description of the lives led by and reactions of some

of the cases studied. The middle of the book is largely an analysis of the statistical material given in the appendix, which reveals that real success, as measured by complete social adjustment, is not to be expected of graduates of the Massachusetts reformatory. However, in the chapter of "Conclusion and Recommendations" the authors point out that improvement of ex-prisoners is likely to continue after their parole period. It is pointed out too that the conduct of these women was usually best during parole. This chapter contains many suggestions likely to shock any snugg socially satisfied citizen who reads it. There remains much room for improvement even in the study of the crime situation as well as in the treatment of criminals themselves. The work that the Gluecks are doing should present to many psychiatrists and other criminologists some concrete arguments calculated to arouse the public into giving them more help in dealing with crime.

L'année pédiatrique Première année (publiée en 1934) Par Robert Broca et Julien Marie. Préface du Professeur Robert Debre. Papier. Price 75 francs. Pp 187 with 46 illustrations. Paris: Masson & Co 1934.

This small volume is comparable to some American yearbooks in medicine. It is free, however, from bibliographic references and is apparently written as a practical review of the recent advances in pediatric subjects not well understood by the average physician in the general practice of medicine. Each subject is treated in a concise textbook manner, with a brief general description of the disease, onset and course, symptomatology, diagnosis, prognosis and treatment. Apparently the authors intend to publish a similar book each year giving recent advances and useful facts on disease not generally known to those in general practice. Among some of the interesting subjects covered are acrodynia, erythema nodosum, Still's disease, meningococcemia, ethmoiditis, lipid nephrosis, acute epiphysitis, Meckel's diverticulum, modern prophylactic measures in measles, pyelitis, vitamin therapy and Hodgkin's disease. The subjects selected appear to be those in which the authors have had some experience. The thoughts expressed and treatment advised are not unlike those seen in recent revisions of American textbooks. The book is recommended to those interested in obtaining current views on some important pediatric subjects written in a concise and practical textbook manner. American yearbooks in pediatrics, however, offer the general practitioner a greater variety of subjects as well as a more effective treatment of them.

The Medical Record Visiting List or Physicians' Diary for 1935 Revised edition. Fold-out. Price 30 patients per week \$1.75. 60 patients per week \$2.00. Patients per week \$2.50. Pp 27 plus memoranda. Baltimore: William Wood & Company 1934.

This book has been available to the medical profession for many years in this form. It fills a well established need providing information concerning dosages, antidotes and artificial respiration, and made up in sizes for the recording of data concerning thirty, sixty and ninety patients. It is compact and well bound and includes a good pencil.

Useful Drugs. A List of Drugs Selected to Supply the Demand for a Less Extensive Materia Medica with a Brief Discussion of Their Actions, Uses and Dosage. Edited by Robert A. Hatcher Ph.D. Sc.D. M.D. and Cary Eggleston M.D. Prepared under the Direction and Supervision of the Council on Pharmacy and Chemistry of the American Medical Association. Ninth edition. Cloth. Price 60 cents. Pp 203. Chicago: American Medical Association 1934.

This book represents a valuable and increasingly effective phase of the efforts of the Council on Pharmacy and Chemistry on behalf of rational therapeutics. Since its first appearance in 1913 it has become a recognized work in its field. It has been adopted as a textbook by teachers of therapeutics in the best medical schools and by various examining and licensing boards. The various editions and revisions since that time have been undertaken in the effort to keep it abreast with the advance of therapeutics. Drugs that have become obsolete have been deleted and others the value of which has become established have been added. The statements of actions, uses and dosage of the various drugs are revised after discussion by the whole Council. They represent the latest and best results of therapeutics and pharmacologic revision. The present edition is in line with the constant aim of the Council which has

been to present a selective and informative yet comprehensive compendium of the more useful preparations in the medical armamentarium. There have been some additions to the list of drugs and a few have been deleted. Individual descriptions show evidence of careful editing. Typographically the text is an improvement on previous editions by reason of more generous spacing, which makes it easier on the eyes. As it stands, the book is an authoritative, intelligent, critical and entirely adequate textbook for the use of teachers and examiners, as well as for reference by the busy practitioner. It is an integral and constructive part of the Council's efforts in the promotion of the rational use of drugs.

The Mather's Encyclopedia. Compiled and Edited by the Editors of The Parents Magazine. One volume edition. Cloth. Price \$3. Pp 957 with illustrations. New York: Reynal & Hitchcock 1933.

The editor of the *Parents Magazine* has compiled from the back issues of that periodical articles on many topics, making a virtual encyclopedia of the child. There is an extensive collection of authors and the topics seem to include every phase of childhood from the physical, mental, social and other points of view.

Rules for Recovery from Pulmonary Tuberculosis. A Layman's Handbook of Treatment. By Lawrason Brown M.D. Sixth edition. Cloth. Price \$1.75. Pp 275. Philadelphia: Lea & Febiger 1934.

Six editions of this book have kept pace with the advancement of our knowledge of the control of tuberculosis. The volume is one of the most simple and practical statements available to the person who has the disease and who is able to approach the problem of his care with some intelligence. It can be unreservedly advised as a safe and useful book.

A Decade of Progress in Eugenics. Scientific Papers of the Third International Congress of Eugenics Held at American Museum of Natural History. New York August 21-23 1932. Committee on Publication: Harry F. Perkins, Chairman; Charles B. Davenport, ex officio; Clarence G. Campbell; Madison Grant; Harrison R. Hunt; Frederick Osborn; Paul I. Lopenoe; Laurence H. Snyder; and Harry H. Laughlin, Secretary. Cloth. Price \$6. Pp 531 with illustrations. Baltimore: Williams & Wilkins Company 1934.

This volume includes the scientific papers read at the Third International Congress of Eugenics. The contributions are roughly grouped on the subjects of anthropometry, race amalgamation, education, positive and negative eugenics, infertility and disease, differential fecundity, and human genetics. The concluding section of the book is devoted to a description of the extensive exhibits, organization and membership and other information concerning this group. Those who are especially interested in eugenics and who endeavor to keep abreast of advances in this field will find this volume most useful.

Aids to Obstetrics. By Leslie Williams M.D. M.S. F.R.C.S. Obstetric Surgeon to Out Patients, St. Mary's Hospital, London. Tenth edition. Cloth. Price \$1.25. Pp 219 with 4 illustrations. London: Baillière Tindall & Cox. Baltimore: William Wood & Co 1934.

In this edition the general arrangement is similar to the previous editions. On the structure the author has rewritten the entire text, bringing it into conformity with modern theory and practice in obstetrics. Several new illustrations have been added and Dr. G. W. B. Jones has collaborated in writing a new section devoted to the mental diseases sometimes associated with pregnancy. The number of times this work has reappeared gives evidence of its usefulness and popularity. It is well done, and the type and paper together with the workmanship, make a durable and serviceable volume for ready use.

Epidemiology in Relation to Air Travel. By Arthur Massey M.D. D.P.H. Medical Officer of Health for the City of Coventry. Cloth. Price 7/6. Pp 59 with 5 maps. London: H. K. Lewis & Company Ltd 1933.

The aerial transportation of mosquitoes is giving concern to epidemiologists who are particularly interested in the spread of yellow fever. The possibility also exists of the transmission of plague, cholera, malaria, relapsing fever or smallpox to those who travel in airplanes through inadequate control of sanitation of aircraft. Dr. Massey presents a brief outline of measures for suitable sanitary control, offering in this way a fundamental book in a new field.

Encyclopædia of Sexual Knowledge By A Costler M.D. A Willy M.D. and Others under the General Editorship of Norman Haire. Ch. M. B. Cloth Price \$6 Pp 636 with Illustrations New York Coward McCann Inc 1934

It appears that this encyclopædia has sold 80,000 copies in France and has had a phenomenal success on the continent. It is issued under the general editorship of Norman Haire, who contributed articles on contraception, abortion and sterilization. It seems to present a good general consideration of the evolution of sexuality, the technic of intercourse, the hygiene of pregnancy, frigidity, impotence and various sexual aberrations and also a consideration of venereal diseases, prostitution and the white slave traffic. The volume contains a good deal of information not available elsewhere under a single cover and for the physician who requires this kind of book is an excellent compendium of the subject.

Medicolegal

Medical Practice Acts Conspiracy to Practice Medicine Unlawfully—Lester Tilton and Harry De Joannis were charged with conspiracy to practice medicine unlawfully. They were convicted the jury fixing their punishment at imprisonment in the penitentiary and a fine of \$2,000 each. The judgment was affirmed by the appellate court for the first district, Illinois (273 Ill App 52) and the defendants carried the case to the Supreme Court of Illinois.

The third count of the indictment charged that the defendants conspired to assist Lester Tilton in holding himself out to the public as being engaged in the diagnosis and treatment of human ailments particularly cancer, and in professing to prescribe for and heal cancer and maintaining an office for such purpose including the examination and treatment of patients having cancer, and in holding himself out as being a physician by using the words 'Doctor,' 'Physician' and the title 'M.D.' Tilton not being a licensed physician. The defendants contended that this count should have been quashed, because it charged a common law conspiracy but enumerated acts which they were charged with conspiring to commit which were not crimes at common law but are only so by statute. Inasmuch as the practice of medicine without a license was not a crime at common law they urged they could not be convicted under a common law form of indictment for a conspiracy to do such acts. But since said the Supreme Court, the doing of the acts charged is expressly forbidden by the medical practice act, it was impossible to find any merit in the defendants' argument. A criminal conspiracy at common law may involve the doing of an unlawful act by any means or any act by unlawful means, and the count under consideration properly charged a common law conspiracy. An agreement to do an act made unlawful by statute may be a common law conspiracy.

The fourth count of the indictment was based on section 46 of the Criminal Code which provides that "If any two or more persons conspire or agree together to do any illegal act injurious to the public health they shall be deemed guilty of a conspiracy. The count alleged that Tilton did not possess a license to practice medicine as required by the medical practice act and that he and others conspired to do certain illegal acts injurious to the public health. The defendants urged that conspiring to hold out an unlicensed person as being duly qualified to treat human ailments is not injurious to the public health that cancer is not a contagious or infectious disease, and although prescribing for it may be injurious to the individual, it is not so to the public in general. The medical practice act, observed the Supreme Court, was designed and intended better to protect the public health. It is as much in the interest of the public health that individuals should be protected from quacks, who have no proper medical qualifications preying on the credulous but incurably sick, as it is to protect congested areas against the sweep of an infection. That the cases may be isolated renders them of no less interest to the public. The gravamen of the offense charged by this count is to be found in the plan unlawfully to hold out to the public that Tilton was qualified and competent to treat cancer

successfully in human beings. It is this public holding out—this seeking for victims from among the general public—that constitutes the public injury, and it is precisely this kind of a public injury that the medical practice act is intended to prevent.

In the opinion of the Supreme Court, the trial court did not err in overruling the motion to quash the indictment or either of its counts. The judgment of the appellate court was therefore affirmed.—*People v Tilton et al (Ill)*, 191 N E 27.

Workmen's Compensation Acts The Femur as a Part of the Leg—For the purpose of fixing the compensation to be paid an injured workman, it became necessary to determine if the femur is a part of the leg. The workman contended that it was not, citing many medical and dictionary definitions of the word 'leg' to the effect that the leg is that portion of the limb consisting of the patella, tibia and fibula, or from the ankle to the knee. We have no quarrel with these anatomical definitions, said the Supreme Court of Arizona, but the question is, 'what does the word mean as used in our compensation law?' We think, continued the court, it is used in the sense of its common and accepted meaning, which is, according to Webster's New International Dictionary, 'A limb or member of an animal used for supporting the body, and in running, climbing, or swimming, sometimes, specif, that part of the limb between the knee and the foot.' The human body, said the court, has two arms and two legs, or four limbs. A complete arm, in common parlance, extends from where it connects with the shoulder blade to the hand, and a complete leg extends from where the ball of the femur fits into the socket of the hip to the ankle or foot. The Supreme Court therefore affirmed an award made by the industrial commission of Arizona from which the employee had appealed.—*Ujevich v Inspiration Consol Copper Co (Ariz)*, 33 P (2d) 599.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to *THE JOURNAL* in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Advancement of Oblique Ocular Muscles—Wheeler submits two operative procedures by which the oblique ocular muscles can be reinserted according to the requirements of the abnormality. The operation on the superior oblique may be used for excessive elevation in adduction, and either advancement or recession of the superior rectus can be done conveniently along with advancement of the superior oblique. The operation on the inferior oblique is especially useful in depression of the globe accompanying ptosis and may in such cases be combined with advancement of the superior rectus. In the operation for shortening the superior oblique general anesthesia is administered. The eye is turned well down by means of a suture attached to the sclera just above the cornea. The conjunctiva is incised in the upper fornix and dissected so as to expose the insertion of the superior rectus. A suture is passed through the superior rectus tendon near its insertion and the tendon is cut between the suture and the insertion. The superior rectus is then allowed to retract and is separated from the underlying superior oblique tendon. A squint hook is slipped under the rather frail superior oblique and a double-needled suture of fine gut or silk is made to loop the middle third of the tendon several millimeters from the insertion. The needles are then carried into the superficial sclera temporalward from the original insertion. During the maneuver, the eye should be held extremely downward and inward. When the double-needled suture is tied the superior oblique is advanced in an amount to correspond to the distance from the points of entry of the needles in the tendon to the points of entry into the sclera. It does not matter whether the tendon is cut off near the original insertion or not. After the superior oblique is made fast to the sclera, the superior rectus is sutured back

in place and the conjunctival wound is closed with fine silk. In the operation for shortening the inferior oblique, either infiltration or general anesthesia is employed. A skin incision about 2 cm. long is made along the orbital margin with the anterior attachment of the inferior oblique at about its center. The dissection is carried through the tarso-orbital fascia into the orbit and the inferior oblique muscle is exposed. The dissection is carried also downward for exposure of the periosteum a centimeter or more below the orbital margin. Two fine chromic gut sutures are passed through the tendon near its anterior attachment while the muscle is held on a squint hook. The tendon is cut free at its attachment and carried over the orbital margin. It is advanced as much as need be and secured to the periosteum on the facial surface of the superior maxillary bone by means of the gut sutures (000). The skin wound is then closed with fine silk sutures.

Neuropathy in Diabetes Mellitus—Jordan and his associates compared the amounts of various lipid constituents of nerves from persons with diabetes with those of nerves from nondiabetic persons. The phospholipid, cholesterol and cerebroside values of diabetic nerves were found to be considerably below the averages found in the "normal" nerves used for controls. The greater the vascular disease present and the lower the level of the nerve examined, the more marked were the chemical changes. The effect of the severity, duration and control (as judged by glycemia and glycosuria) of the diabetes was slight or vitiated by other factors. Occasionally marked variation occurred, unexplainable on the basis of vascular disease or of the known features of the diabetes. The lipid abnormality appeared in the absence of clinical evidence of neuropathy but the degree of the abnormality increased as the clinical signs of neuropathy progressed. The small number of cases and the many variables make the deductions unreliable. Work is being carried on to correct this.

Second Positive Wave of QRS Complex—Katz and Slater state that of approximately 8,000 serial cardiographic records 320 revealed a positive variation involving the terminal portion of the S wave in lead III. The data in fifty are reported, with necropsy records in three cases. From a critical analysis of these records it has been repeatedly observed in lead III that following an R wave there is a downwardly directed (negative) S wave, the upward limb of which rises to a variable distance above the iso-electric line in a sharp peak or summit and then descends with varying rapidity and a downward convexity to the iso-electric line, forming thereby a separate and distinct positive wave. This wave may be sharp, pointed, slightly slurred or rounded at its apex, the catarcotic limb may be thickened or feathered. The height to which this wave mounts is variable and at times may exceed the height of the preceding R wave in the same complex by

as much as 5 mm. The contour of the descent of the wave is likewise variable, it may be a sharp and straight declivity merging at once with the so called ST segment or it may descend gradually to the iso electric line in a curving manner with a downward convexity. In its descent, the trough of the wave may occasionally reach a level of from 0.5 to 1 mm above or below the iso-electric line, rarely there may be a respiratory variation in its amplitude. Left axis deviation is found in each case. A Q wave, in the ordinary sense, is not present. The nature of the ST segment or the height and direction of the T wave that follows bears no relationship to the wave described.

Cryptomyces Pleomorpha—Gruner isolated an organism from the blood in a case of carcinoma of the breast with intrathoracic metastasis. The organism was detected in the circulating blood by direct examination and among the tumor cells in the original neoplasm, in sections that had been made four years previously. Though in part resembling other fungoid organisms that have been described before in human pathology, this one seems to present additional features. Observations of the living cultures have shown that in some phases this organism mimics the cell elements of human blood, the so-called Plummer bodies and Russell fuchsinophil bodies of some malignant tissues and has forms that are like the free nuclei and various sized granules found in many sections of neoplasms. These mimeries explain how the organism may effectually escape detection in the routine observation of tissues and blood. The cultures after passage through infected rats and mice showed a dominantly blastomycetic form, with mycelial formation almost negligible. The reasons for the author's belief that the organism is single are (1) the constant occurrence of the dual forms in succession, at the same time intervals in all subcultures (2) the ability actually to observe the one form changing into the other, (3) the inability to separate them

permanently by plating, (4) the cultural characters, (5) the possession of pathogenicity, (6) its unique character and (7) the unlikelihood of a chance admixture of distinct organisms resulting in such a close symbiosis as actually to manifest conjugation. In the animal lesions produced, the organism is found closely mingled with the reactive infiltration of predominantly monocyctic type and shows in the sections appearances that strongly recall those seen in sections of carcinomas and sarcomas, though such particles are usually regarded as unsentinel bacterial or degenerative components. The name given the new organism is *Cryptomyces pleomorpha*, and it is placed among the ascomycetes.

Histamine in Diagnosis of Achlorhydria.—Mathewson compared the stimulating effect on gastric secretion of a 0.25 and a 0.5 mg dose of histamine, on a selected group of patients, with the object of determining whether the smaller dose of histamine would detect the presence of achlorhydria as accurately as the larger dose. In cases of normal or average sensitivity of the gastric secretory apparatus the 0.25 mg dose of histamine is an effective stimulus, producing a response approximating that of the 0.5 mg dose. This compares favorably with that of Gompertz and Cohen, who employed even smaller doses. These investigators found that histamine hydrochloride in a dose of 0.25 mg was an effective gastric secretory stimulus. In cases of pseudo achlorhydria in which there is apparently a hyposensitive gastric secretory mechanism the 0.25 mg dose of histamine produced a decidedly smaller volume of secretion and a lower acid response than the 0.5 mg dose. The 0.25 mg dose of histamine is definitely less accurate in determining the presence of achlorhydria than the 0.5 mg dose. In clinical tests, in which the possibility of achlorhydria is to be considered no dosage less than 0.5 mg of histamine should be employed. It is advisable to quote dosages of histamine definitely in terms of histamine base, regardless of the preparation used.

Reductions in Congenital Dislocation of Hip—Kidner
compares the results of twenty-six cases in which thirty-four congenital dislocations of the hip were reduced by open operation with thirteen cases in which twenty-two dislocations were reduced by the closed method. The results of closed reduction, even in very young children, are often unsatisfactory, although the only perfect end result from the clinical and roentgenographic standpoints falls in this group. Force should never be used to obtain reduction. Except in rare cases the anatomic changes inherent in congenital dislocation require open surgical treatment if reduction is to be permanently satisfactory. The results of open reduction are better than those of closed. A small incision which does little damage to the soft parts or muscle attachments is sufficient. Adhesion of the capsule to

the side of the ilium is the major factor in preventing reduction, and actual muscle contraction, except in the older cases, does not interfere with reduction. The period of immobilization in a plaster cast is much shorter after open reduction than after the closed method.

Tibial Peg Shelf in Congenital Dislocation of Hip—
Compere and Phemister state that a shelving operation is indicated in congenital dislocation of the hip when open reduction is accomplished and the acetabulum is too shallow, in older cases when the femoral head cannot be reduced, and after closed reduction when with usage the acetabulum proves to be inadequate. This operation is indicated also in the case of a congenitally inadequate acetabulum in which, during adult life, the hip becomes painful. The authors report a case in which three tibial peg grafts were used for the construction of an acetabulum. They have employed the tibial graft shelving operation in fourteen other cases of congenital dislocation of the hip and in five cases of pathologic dislocation following pyogenic arthritis with destruction of the head and the neck of the femur. This shelf creates a more firmly anchored and a heavier shelf than that made from the ilium. Wright extension or pin or wire fixation of the femur to the cast is not necessary. The periods of immobilization have been shortened and upward displacement of the shelf has not come about. The range of motion has been about as great as that obtained after the iliac-shelf operation. The operation necessitates two incisions. However, if one operating team removes the grafts while another exposes the hip, reduces the dislocation and prepares the field, the time is reduced to about that required for constructing an iliac shelf.

Operation for Ununited Fracture of Neck of Femur—
Colonna performed a new type of operation in six cases of old ununited fracture of the neck of the femur, the youngest patient being 48 years of age and the oldest 70. A curved incision is made, beginning about 1 inch behind the antero-superior spine and curving downward and crossing the femur about 5 inches below the tip of the greater trochanter. The fascia is divided and all muscles attached to the greater trochanter are cut near their insertion care being taken not to remove any portion of the underlying bone but to leave the upper extremity of the femur covered by a thin layer of muscle and fibrous tissue. The capsule is then opened longitudinally, after which it is divided transversely close to the greater trochanter, to preserve as much of the capsule as possible. The limb is then rotated outward and adducted, the upper extremity of the femur is freed by sectioning the piriformis, gemelli and obturators close to their insertion. The loose head is then removed and the cervicotrochanteric region is inspected. If spicules of the fragment of the neck remain, they are chiseled off flush with the inner surface of the shaft and this raw area is covered over with adjacent tissue. After the greater trochanter has been completely freed of all its muscle attachments, it can be easily pulled down and placed deep within the acetabulum. The thickened capsule and abductor muscles are then pulled down, holding the limb in about 20 degrees of abduction. The fibers are separated subperiosteally, exposing the shaft of the femur. A bony trough is made on the lateral aspect as far down as the abductor muscles (removed from the greater trochanter) will reach when the limb is in about 20 degrees of abduction. Before the bony flap is prepared, care is taken to have the patella pointing upward. Two small drill holes are then made in the shaft in the antero-posterior plane the muscles are drawn down snugly to this position and held in place by kangaroo tendon and the bony flap is sutured over the mass. The vastus lateralis is then carefully reefed over the new insertion of the gluteus medius and the gluteus minimus and the wound is closed in layers. A long plaster spica cast is applied from the toes to the axilla with the limb in about 20 degrees of abduction and in complete extension. After four weeks the plaster is bivalved, and active and passive movements are begun in bed. This is continued for several weeks and is combined with baking and massage of the muscles of the thigh and hip. Eight weeks after operation the patient is usually able to walk about with the aid of crutches.

Psychologic Factors in Etiology of Diabetes—Menninger studied the psychologic factors in twenty two cases of mental disorder associated with diabetes which in every instance sought medical attention because of the mental symptoms although several had had medical treatment for the diabetes previously. The evidence gained from this study indicates that diabetes may be the direct result of psychologic disturbances. Conservatively five of these cases show such an origin of the diabetes. The close parallelism of the metabolic disturbance to the mental disturbance suggests to the author that this metabolic disorder may also be the result of the emotional conflicts. Certainly the psychologic factors greatly influence the course of an established diabetic state.

Dangers of Acidifying Salt Therapy in Urologic Cases—Oppenheimer points out in cases of alkaline infections of the bladder that in spite of large doses of acidifying drugs, such as acid sodium phosphate and ammonium chloride the urine obtained from the drainage tube remains alkaline. The reason for this continued alkalinity is the local infection of the bladder. In such cases, to persist in treatment with acidifying salts is to incur the risk of acidosis. Listlessness, drowsiness and even coma are sometimes induced. Renal insufficiency is commonly blamed when it may be no more than contributory. The patient is really in acidosis brought about by the ingestion of acidifying salts. In such cases, measures that abolish the acidosis quickly relieve the patient of his alarming symptoms. Serious acidosis does not follow the usual therapeutic dose of 8 Gm of ammonium chloride daily given in four divided doses if renal function is good. This dosage however, given to a patient with impairment of renal function may produce severe symptoms. The author has seen four cases in which the use of ammonium chloride in amounts not excessive for a normal

person led to acidosis. The salt was employed in one case with cardiac insufficiency for its diuretic effect and in three urologic cases for its acidifying effect on the urine.

Repair of Urinary Incontinence—Abeshouse states that the development of complete urinary incontinence following prostatectomy is due to the total destruction or derangement of both the internal and the external vesical sphincters. Various anatomic defects or pathologic lesions about the posterior urethra and vesical neck may be associated with the loss of function of both sphincters. Transplantation of the gracilis muscle has yielded excellent results in the treatment of incontinence. In two cases the author employed the operative technique originally described by Plaver and Callander. The results obtained by transplantation of the gracilis were satisfactory. In one case complete urinary control during the day and night was restored. In the other case complete control was restored during the night and in the reclining posture, but there was partial diurnal incontinence manifested by the leakage of some urine on the patient's assuming the upright position and following excessive muscular effort.

Complete Rupture of Urethra—Watson carried out the following procedure in three cases of complete rupture of the urethra in which the convalescence was uneventful. One patient has been free from stricture formation for eleven years and now has a clear urine free from infection. The second patient had no stricture, was under periodic observation for one and one-half years and was then lost track of. The third patient has been under observation for nine years and has a clear urine, free from infection but has a moderate stricture, which is dilated every three months to number 24 F with flexible bougies. The patient was placed in the exaggerated lithotomy position after suitable skin and genital sterilization, and a wound was placed as far as it would go gently in the urethra. An inverted U incision was then made in the perineum. The levator ani muscles were pushed back and the transversus perineae muscles were brought forward. The central tendon of the perineum was cut across and the anterior end of the urethra located. This was then freed up to its distal point care being taken to preserve as much of the urethra as possible. The rectum was then pushed back and the end of the prostate identified. The hardened scar tissue about the prostatic opening or about the urethra was excised. A number 28 catheter was then placed through the urethra bridging the wound and into the bladder. The freed end of the anterior urethra was pulled down as far as possible toward the prostatic portion. There still remained an unbridged portion of about 1½ inches. At this point two flaps were cut, one out of each side of the anterior urethra. A base attachment to the anterior urethra was maintained in each instance and the freed flap was rotated to permit its distal end to be sutured to the prostatic urethra. Three submucosal supporting sutures were then placed round the flaps, the catheter being used as a splint. The periurethral tissue was then built up round the anastomosed portion. The levator ani muscles were brought together and the skin and subcutaneous tissue closed with an oil silk drain carried down to the periurethral layer and brought out of the lower angle of the wound.

Liver Glycogen Following Experimental Thyroid Feedings—Frazier and Frieman show in experiments on guinea pigs that the rate and degree of the glycogen depletion bears no direct relation to the number of days over which thyroid feeding has been continued. If in man similar events take place the importance of anesthesia and other factors that still further deplete the liver glycogen and prepare a fertile soil for serious hepatic degeneration must be kept in mind. The ineffectiveness of iodine on the circulating thyroid hormone as pointed out by Kunde is substantiated. Their experiments furthermore show that as long as the thyroid hormone gains access to the blood stream the liver stores of glycogen continue to be reduced markedly. The observations of Marine and of Frazier and Mosser that the beneficial effect of iodine in hyperthyroidism is the result of its effect on the thyroid itself would seem to be strengthened. Operation for hyperthyroidism throws an additional load on glycogen stores which are reduced in severely ill patients even under the best of conditions. Therefore the value of attempting to restore the liver glycogen by the judicious use of carbohydrates immediately after operation should be emphasized. The intravenous method offers the most rapid means in patients very ill after operation.

Lycopodium Granuloma—Erb reports six cases of lycopodium granuloma in which the spores were obviously introduced into the tissues during previous operative procedures. In four the resulting lesions bore a striking resemblance to tuberculosis with which they might easily be confused. Two of the patients developed intestinal obstruction from adhesions at the site of a previous operation and there is reason to believe that these were caused by the lycopodium spores. The author says that the use of lycopodium spores as a dusting powder in operating rooms should be discontinued. The reaction is essentially a foreign body one the spores having been killed by sterilization previous to introduction into the tissues. The fact that the spores are acid fast, as are also tubercle bacilli, and that the lesions produced by the spores are almost identical with tubercles even to the production of caseation leads the author to believe that the chemical composition of the spores may be an important factor in determining the type of reaction. While the presence of the spores in some instances

may give rise to little or no inconvenience to the patient they may lead to serious errors in diagnosis, which may result in radical or unnecessary surgery.

Ulcer Following Gastro-Enterostomy—From January 1928 to January 1933, Hinton and Church observed 583 cases of peptic ulcer and of this group 440 patients were not operated on at the time of admission. Of the 143 patients who had been operated on before entering the clinic, ninety had been operated on for chronic ulcers and seventy-nine of these had had gastro-enterostomies performed. Of this group thirteen patients had gastrojejunal ulcers which is 16.4 per cent of marginal ulcers occurring in the gastro-enterostomies during a period of five years. Of the thirteen patients five were operated on in hospitals in or round New York and eight were operated on at Bellevue Hospital no two patients were operated on by the same surgeon. From the review of the cases the authors feel that any conclusions drawn as to the percentage of gastrojejunal ulcers developing after gastro-enterostomy is most inaccurate unless the patient has been followed for a period of ten years and also seen at frequent intervals, with repeated roentgen examinations. Three of the patients who came to operation developed symptoms of a marginal ulcer after seven years and one ten and one-half years following gastro-enterostomy. When one realizes that the majority of the patients have been followed less than five years and that in seventy-nine gastro-enterostomies thirteen gastrojejunal ulcers developed and that of the thirteen cases three occurred after seven years it would seem that a ten year follow up is necessary in drawing conclusions as to the percentage of gastrojejunal ulcers. Gastrojejunal ulcers run the same course as do peptic ulcers. Too much dependence should not be placed on a negative gastro-intestinal examination for patients frequently will have a marginal ulcer in spite of several negative gastro-intestinal series. Medical treatment should be tried for as long a period as the patient progresses satisfactorily, because marginal ulcers will get symptomatic relief from conservative treatment the same as will any peptic ulcer. If the patient continues to have severe pain under medical treatment, it usually means that the marginal ulcer is perforating into some adjacent viscus the pancreas and transverse colon being involved usually. For this reason it is best to submit a patient with a gastrojejunal ulcer suffering severe pain to a second operation rather than to continue medical treatment if pain is not relieved or improved promptly under conservative treatment.

The Dick Test and Measles Complications—Taylor studied the complications occurring in 227 cases of measles with reference to the Dick reaction of the patients. A positive reaction to the Dick test was used as an indication of a lack of circulating streptococcus antitoxin. In the majority of cases a single test was performed during the first week of the disease. The hemolytic streptococcus is undoubtedly responsible for a number of serious complications in measles. In some infections the toxic effects of the organism are overshadowed by its invasive activity and the use of antitoxic serum deficient in antibacterial action is likely to be followed by disappointing results, and the serum itself may thereby be unfairly discredited. The most striking feature of the results is the difference in the death rate, which is not proportionate to the difference in the incidence of pneumonia between the two groups. Anti-streptococcus serum would be most effectively employed not so much in the prevention of pneumonia as in preventing the streptococcus from invading the lungs when pneumonia is already present. One cannot expect the serum to cure pneumonia due to organisms other than the streptococcus. If it protects the lungs against secondary infection with streptococci, its use may be considered to have been successful, even when no dramatic improvement in the condition of the patient is noticed at the time of injection. The Dick reaction would be of only limited value in the selection of cases for treatment as a positive reaction is sometimes suppressed in the early stages of the disease and it is at this time that serum treatment would presumably be most effective. The clinical condition of the patient would probably be a better guide than the Dick test. Although it is not possible to forecast the course of the disease accurately, there are some cases in which from the beginning there is a fair degree of certainty that the disease will run a severe and possibly fatal course and these would seem to be the most suitable cases for serum treatment. The figures for otitis media do not encourage the belief that this complication can be prevented to any great extent by serum injections. The number of cases of laryngitis is too small to justify any conclusions. There is a fairly general opinion that anti-streptococcus serum is of great value in relieving the local condition in the larynx and the result of treatment of the laryngitis cases that the author mentions is in accordance with this view.

*Treatment of Erysipelas by Ultraviolet Light N E Titus—p 150

Treatment of Erysipelas by Ultraviolet Radiation—Titus states that timidity in the treatment of erysipelas with ultraviolet radiation has kept down the dosage. He states that an increase of the dosage up to twenty times the erythema dose

has proved conspicuously successful. In competition with other forms of treatment, ultraviolet radiation has produced quicker and more complete results. The exact method by which the cure of erysipelas is attained is as yet undetermined. The author suggests four paths of research, all of which in their basis disregard any traditional bactericidal action of ultraviolet energy. It seems more rational to disregard ultraviolet radiation for any bactericidal action in vivo. Its use in the treatment of erysipelas can be credited as having withstood the test of time and its usefulness is attested by its universal effectiveness. In modern therapeutics ultraviolet radiation is widely available, easy to administer and on account of its quick action is of economic value because the patient can be removed from general precautions much more quickly.

Roentgen Kymography of the Heart—Stumpf believes that because of the complexity of the movements of the heart a graphic method of kymography which records the movement of only a few points of the cardiac contour is not sufficient. The kymographic examination with many narrow slits serves the purpose of giving a good record of the changing contours of the entire shadow of the heart. The kymogram permits the determination of the extent, duration and relationship of the movement of various portions of the heart. It permits the topographic differentiation of the various structures that go to make up the median shadow. The functional significance of the varied movements may be determined by a study of their relationship to one another. The type of cardiac movement is individual and varies. However, the zonal distribution of regions of hypertrophy (ventricles and atrophy of the apex) may be determined. The variation in the type of movement is associated with functional changes. There are individual variations in the characteristics of the movement. Strong and weak heart actions, however, show characteristic pictures. The time relationships of the movements as shown by the kymograph may be determined with precision by a densographic method. It is particularly valuable in the analysis of the types of movement. The correlation of the time relationships is of great value in pathologic conditions. Valvular diseases are not always associated with characteristic wave changes. On the other hand myocardial changes even of minor extent definitely modify the character of the movement of the ventricular chambers.

Technic for Cure of Epispadias in Women—Mercier performed an operation for the cure of epispadias in a girl of 17 in whom the urethra opened behind the symphysis and was no more than a sixth of an inch in length. The labia majora, the labia minora and the clitoris were separated by a furrow. On each side of this furrow, at the end of the labia minora, there was a stump appearing to be a vestige of an incompletely formed sphincter. Roentgen examination showed no separation of the pubic bones. The operation provided the elongation of the urethra as well as its narrowing and it restored the internal sphincter. The technic was a modification of Marion's. To provide the elongation of the incomplete urethra, a flap was dissected from the anterior wall of the vagina. Each side of this flap was fixed to the corresponding side of the furrow. Thus the internal part of this new canal was formed with the mucosa of the vagina. The new urethra having been shaped, the lateral stumps, which seemed parts

of an incomplete sphincter, were sutured together in the median line, as one would proceed for the cure of the cystocle. The lateral dissection was deeper and the sutures were placed as far as possible on each side. Reconstruction of the labia and of the clitoris completed the operation. After this radical procedure, the bladder was drained by means of a cystostomy. No catheter was placed in the new canal before the fifteenth day. On that day the cystostomy tube was removed, and a soft catheter was introduced into the new urethra and left until the suprapubic wound healed completely. Eighteen days after the operation the suprapubic wound was healed and the patient was able to urinate normally and to hold urine perfectly. The functional result is still perfect. The author believes that the success obtained depended on the fact that the tissues of the incomplete sphincter were brought together to surround a reformed urethral canal.

Spondylitis Traumatica (Kummell's Disease) Case R Drummond —p 510

Gastrectomy and Gastro-Enterostomy Anemia—Hartfall states that the anemia following gastric operations is usually hypochromic, is commoner in women, is usually progressive and is most frequently encountered between the ages of 40 and 50. It is independent of the amount of stomach removed and the presence of histamine acidohydria. The clinical features associated with the anemia are similar to those encountered in idiopathic hypochromic anemia, including in the more severe cases slight splenomegaly, glossitis and dystrophy of the skin and nails. Roentgen observations show that a considerable degree of gastro intestinal dysfunction is present in the majority of cases. The importance of rapid gastric and small intestine evacuation is mentioned. The symptoms complained of are chiefly gastro-intestinal and the incidence of abdominal pain, vomiting and diarrhea supports the view that a severe grade of gastro-intestinal dysfunction is present. Recurrent peptic ulceration is an infrequent contributing factor. Extreme modifications of diet are commonly encountered and are usually adopted to lessen the severity of gastro-intestinal symptoms. A survey of the dietary in twenty-five of the most severe cases shows that it is inadequate for maintenance of normal blood regeneration. It is grossly defective in both mineral and vitamin content. In the milder cases it was found that the hemoglobin defect could often be made good up to a point with iron and ammonium citrate. Sometimes further improvement can be achieved by the addition of a vitamin B rich substance, such as wheat germ or dried yeast. In the severer cases the treatment instituted was as for peptic ulcer. Additional sources of vitamins were given especially vitamin B. To prevent the development of chronic anemia, knowledge of the behavior of the gastro-intestinal tract after surgical intervention is indicated. The powers of adaptation to the new conditions need to be determined in those who may be regarded as complete surgical successes as well as among the failures. In this way it may be possible to avoid the causes of failure. The regular employment of one type of operation for similar cases must inevitably carry with it a certain number of failures. The ideal operation for the individual patient will be achieved only if he is subjected to a physiologic as well as a pathologic study in the preoperative period.

Heat Production in Man—Adams and Poulton point out that a comparison of the reported values for measured and calculated heat under basal or standard conditions shows that there is a fundamental error in the theory of the variable combustion ratio in which the respiratory quotient indicates the proportion of carbohydrate to fat that is being oxidized in the body. At high values of the respiratory quotient the calculated results are too low and at low quotients they are too high. If direct heat and carbon dioxide are plotted against each other

in one diagram and heat and oxygen in another there is a closer relation between the heat and the carbon dioxide than between the heat and the oxygen. The authors suggest that carbon dioxide should be taken as the basis of indirect calorimetry.

Serologic Classification of Streptococcus Pyogenes—Griffith states that the hemolytic streptococci associated with scarlet fever, tonsillitis and septic conditions belong to one group or species designated *Streptococcus pyogenes*. Cultural and serologic aids for the identification of *Streptococcus pyogenes* are described. The epidemiologically significant types of *Streptococcus pyogenes* appear to be about twenty in number, though probably more than thirty types of serums will be necessary for the complete analysis of the group. So far twenty-seven individual serologic types have been defined. The irregularities that have been observed in the agglutination reactions of streptococcus cultures are ascribed chiefly to variations in type specificity. Different colonies may give type specific or group agglutination, and these distinctions are revealed macroscopically in the case of certain types by growth on homologous agglutinating serum agar. The principles involved in the serologic classification of a bacterial group are discussed.

Cerebrospinal Fluid in Mental Deficiency—Paddle examined the cerebrospinal fluids in 2000 cases of mental deficiency of both sexes all grades and ages. In 1,500 of these cases, observations were made on the after-effects of lumbar puncture. Postlumbar puncture symptoms developed in 17 per cent of these, vomiting in 14.2 per cent, headache in 6.8 per cent and pyrexia up to 101 F in 0.73 per cent. The incidence of vomiting was nearly twice as high in women as in men, being 20.1 and 10.5 per cent. It was also higher in the feeble-minded group

than in the imbecile or idiot group. There was a direct relationship between the rate of flow of the cerebrospinal fluid and the incidence of postlumbar puncture symptoms. When the former was rapid, the incidence tended to be high, when it was slow, the incidence was relatively low. The tests used on the cerebrospinal fluid were the Wassermann cell estimation, Pandy, colloidal gold and the acetic anhydride test of Boltz. Many pseudopositive Pandy and Boltz reactions were given by the fresh cerebrospinal fluid. Of the 2000 cerebrospinal fluids examined, fifty-five were abnormal. The Wassermann reaction was positive in nineteen cases, excess of cells existed in thirty-two, excess of globulin in forty-four and the colloidal gold reaction was positive in thirty. Of congenital syphilitic patients 23.9 per cent had abnormal cerebrospinal fluids. The incidence of abnormal cerebrospinal fluids was higher in those cases of mental deficiency complicated by epilepsy or paralysis than in those free from such complications. The cerebrospinal fluid of only one out of fifty-four mongolian defective patients gave a positive colloidal gold test. In the remaining fifty-three the cerebrospinal fluid was normal in every respect.

Treatment of Epidermophyton Infection—Whitfield believes that in the absence of infection of the nails, which increases the difficulty of the problem immensely, cure may be obtained in the great majority of cases of epidermophyton infection. He has had numerous cases in which symptoms have not recurred after periods up to fifteen years after the cessation of treatment. The actual treatment of the disease

may be considered from three points of view: the prevention of infection in previously healthy persons, the prevention of reinfection in the patient and the actual treatment of the existing disease. He discusses the use of iodine, chrysarobin, benzoic acid, Castellani's fuchsin and resorcin paint, potassium permanganate, the heavy metals and sulphur in the treatment of the infection.

Lupoid Variety of Cutaneous Leishmaniasis—MacLeod reports a case of the lupoid variety of cutaneous leishmaniasis in which the nodules seemed to have resulted from a spread of infection along the lymph canals from the original focus. A dissemination of the organisms may also take place by way of the blood stream when a generalized outbreak of cutaneous lesions has occurred in cases of kala azar treated with antimony injections and occasionally in untreated cases. The cutaneous generalization in leishmaniasis corresponds to the so called exanthematous type of lupus vulgaris in which, from the breaking down of some internal focus such as a tuberculous gland, generally as a result of measles, multiple lesions of lupus vulgaris appear widely distributed over the cutaneous surface. The diagnosis of the lupoid form of leishmaniasis from tuberculosis may present considerable difficulty but it is generally aided by the history of the lesion having followed the bite of a fly which is practically never the case in tuberculosis of the skin. The type of cellular infiltration may be so similar in the two that it is impossible to base their differentiation on their microscopic appearance alone, and the final decision must rest with the demonstration of Leishman-Donovan bodies in sections or in the serum aspirated from the lesion by a fine pipet. When Leishman-Donovan bodies are present they are usually in profusion whereas in tuberculosis of the skin the bacilli are as a rule so sparsely distributed that many sections may have to be examined before one or two bacilli are discovered within or about a giant cell. This type of leishmaniasis does not respond satisfactorily to injections of antimony possibly because the organisms themselves are not active and some of them may even be degenerated; consequently it is best to treat it locally in much the same way as lupus vulgaris. Excellent results are obtained by curet tage or by cauterization and as the infiltration is so well defined and does not extend into the subcutaneous tissue, it can be destroyed with little or no scarring.

Periodicity of Microfilaria Bancrofti—Lane is of the opinion that much of the so called knowledge of infection with periodic Wuchereria Bancrofti in man is assumption. The central assumption is that in cyanide poisoning the flow of lymph ceases on death whereas Drinker has found that the postmortem flow in this condition is considerable in duration and quantity. It was essentially on a death from hydrocyanic poisoning that Manson based his hypothesis that in the periodic form of this filariasis microfilariae hide themselves by day in just those positions to which a postmortem flow of lymph would carry them. His hypothesis is left without foundation. On the other hand O'Connor reports that he has demonstrated precisely that anatomic condition which must be found in female worms if periodicity is produced by their simultaneous parturition and typical appearances of the worms at essential stages have been shown. As always in such cases, his work must be repeated by others but in the meantime theoretical objections by those who neglect to further this study cannot indefinitely be taken seriously. Analogies with Dirofilaria immitis are inexact and must not be given undue weight. The proper material for the study of this periodic filariasis of man is man with this periodic filariasis.

Desensitization and Nonsensitivity by Habituation—Arlong and Langeron believe that true desensitization to protein shock does not exist, but that an organism is rendered temporarily refractive. The absence of specific factors in anti-anaphylactic agents, as, for example, the action of peptone against the shock of another peptone, suggests to them the hypothesis that a state of nonsensitivity may result from habituation to repeated shock rather than true desensitization.

Tracheotomies During Cervicothoracic Operations—Capelle shows that space-limiting processes in the cervico-thoracic region (usually caused by deep-lying goiters) press on the trachea. The softened tracheal cartilages bring on the danger of acute suffocation (bending or inspiratory collapse of the tracheal wall). Mild forms of asphyxia due to these causes can be overcome by overpressure respiration (Sauerbruch), but the more severe forms require surgical aid. To be free from such complications during surgical interventions it has been recommended that the operation be performed while the tracheoscope is in place. If during the operation it becomes evident that complications may develop later, the surgeon will try to produce a support for the trachea. Kocher did this by a suture Sauerbruch by suspension of the goiter stumps on the sternocleidomastoid muscle. However, in stenoses that are located below the level of the attachment of the sternocleidomastoid muscles Sauerbruch's method is not suitable. Asphyxia may develop also after the operation in cases in which this could not be foreseen. In these cases it appears most reasonable to perform a tracheotomy in the reopened operative wound. However, the prognosis of the patients who have been tracheotomized in this manner is extremely unfavorable. The post-mortem examination often reveals generalized sepsis. In view of this fact the author raises the question whether it is permissible to perform a tracheotomy through a new operative wound. He thinks that the danger of an extensive wound infection might be prevented by opening the trachea higher up at a site removed from the surgical region and that the stenosis might then be overcome by means of long flexible catheters. He points out that, in postoperative asphyxia tracheotomy is frequently postponed too long.

Resection of Artery and Unilateral Adrenalectomy in Endarteritis Obliterans—Donati reviews the opinions of others on the value of resection of arteries and of adrenalectomy in endarteritis obliterans. He reports a case in which arteriography had shown that the largest vascular trunk was closed and that only the branches of the deep femoral artery became injected. The fluctuation index was zero. Complete obliteration of the femoral artery had been proved. Arterectomy of the femoral artery had an immediate effect on the pain as well as on the temperature of the member. Subsequent removal of the left adrenal gland improved the effect further. About ten months after the intervention the circulatory conditions were improved to such an extent that blood pressure which formerly had not been perceptible in the affected leg was now measurable. The increase in temperature persisted trophism was

satisfactory, and the wound, which had remained open for several months, was now permanently closed. The patient was able to resume his occupation, which compelled him to stand for long periods. The author believes that adrenalectomy promotes the effect of arterectomy in an extremity in which severe trophic impairment has already developed. This case confirms the harmlessness of the resection of a rather long portion of the obliterated femoral artery and shows that arterectomy combined with unilateral adrenalectomy, performed in two stages is of value in endarteritis obliterans.

 *Hemoglobinuria Due to Plasmochin Case L Ficacci—p 136
 Cholecystography in Diabetic Patients G Zappalà—p 139

Hemoglobinuria Due to Plasmochin—Ficacci refers to a man, aged 25, with a history of malaria and bronchial catarrh, who was under observation for recurrence of the malaria. Oral administration of 0.16 Gm of plasmochin during several days was well tolerated by the patient. When, however, 0.18 Gm of plasmochin was orally administered for a period of three days, symptoms of hemoglobinuria (fever, icterus, urobilinuria) developed. Subsequent administration of 5 Gm of quinine for a three day period did not produce any disturbance. The author concludes from this that the hemoglobinuria was produced by the plasmochin and that the line between toxic and medicinal doses of plasmochin is narrow.

Dietetic Treatment of Peptic Ulcer—D Amato's treatment of peptic ulcer is as follows. The first week the patient is fed solely on white of eggs, butter and sugar. The amount of white of eggs that the patient takes varies between eight and fourteen daily, distributed in four or five feedings. The white of eggs is taken alone without any modification and on an empty stomach. The amount of butter taken by the patient should be 100 Gm daily distributed in four or five feedings. The butter should be made up into sugar coated pills and given at least fifteen minutes after the white of eggs has been taken. The patient may have plenty of weak tea with sugar. At least 100 Gm of sugar a day should be taken. The same diet is continued during the second week with the added juice of ten oranges and the juice and pulp of ten tomatoes of medium size. These two foods are taken just after the butter or a little later, but not when the ingestion of the white of eggs is near. From the third week on a gradual diminution of the amount of white of eggs and of butter, an increase of the diet and a gradual change to other foods should begin. In this week the patient may receive fresh vegetables, cereals, fruits, fresh brewers yeast and some other foods, such as beef bouillon with oats rice soup whole wheat soup, potato puree and baked sweet potatoes eaten with salt and butter. The yeast is dissolved in a tablespoonful of beer and taken with each meal. The fourth week the patient should be given some yolks of eggs, whole wheat bread and fruits. The egg yolks may be taken alone or beaten in a small amount of wine sweetened with sugar. The bread may be eaten plain or toasted with butter. The fruits should be eaten raw, with a preference for oranges, bananas and plums. Lemonade may also be taken. The fifth and sixth weeks the patient may have calf's liver, sheep or calf brain and a little pork. These foods should be cooked or fried in lard or beef fat not in oil. By this time he may also have nuts. After the sixth week the patient gradually goes on a general diet avoiding, however, foods containing little or no vitamins such as sterilized flours, decorated cereals, olive

oil, oleomargarine, creamless cheese, preserved meats, white fish, wine, beer, tea and chocolate. This diet may be given for a length of time suited to the case. It results in the stopping of pain and of recurring acute crises. The treatment, whether alone or with the aid of medical therapy, gave satisfactory results in uncomplicated peptic ulcer. Sometimes it resulted in the cure of the patient. It also proved satisfactory when used preoperatively in peptic ulcer presenting complications. The author reports more than 100 cases in which good results were obtained.

Thyroid and Ovary—Loeser explains by experiments the efficacy of di-iodotyrosine in menopausal disturbances. The removal of the ovaries from female guinea-pigs is followed by a morphologically demonstrable hyperactivity of the thyroid, which is due to the fact that the anterior lobe of the hypophysis produces more thyroid active substance. This excess in the secretory activity of the anterior hypophysis and the morphologic signs of thyroid hyperactivity produced thereby can be suppressed by oral administration of di-iodotyrosine. The point of attack of di-iodotyrosine is the anterior lobe of the hypophysis.

Relation Between Gonads and Other Endocrine Organs—Eng describes the clinical history of a woman who died of adrenal insufficiency. Especial attention was given to the elimination of hormones. It is worthy of note that the condition of the patient took a turn for the worse following menstruation and particularly after the onset of pregnancy. It is possible that the endocrine disturbances during menstruation and pregnancy had some influence, however, it would have been impossible for the woman to live much longer with the adrenal function practically extinguished. The author indicates in diagrams the results of the urinalysis for the presence of hormones. During the woman's first stay at the clinic her hormone elimination was normal while during the second stay when she was pregnant it was somewhat reduced. A comparison of the clinical observations with the results of the hormone analyses indicates that these permit no conclusions regarding a connection between the patient's general condition and the sexual functions.

Carotene and Vitamin A Metabolism—Wendt reports clinical and experimental studies. Serum analysis of healthy persons revealed for carotene an average of 86 Lovibond units (yellow) and for vitamin A an average of 14 Lovibond units (blue). In healthy persons the carotene and the vitamin A contents proved to be subject to considerable fluctuations. In prolonged feeding experiments with carotene and vitamin A, the carotene and vitamin A contents did not increase further, once they had reached a certain maximum. It was found that some organs stored carotene and vitamin A. The author's experiments corroborated the observations of Juszat, who found that following the administration of vitamin A to rabbits there develops hyperlipemia and hyperlipodemia. However, it proved impossible to increase the fat content of the serum of dogs by treatment with vitamin A. In human subjects the results varied. In disorders in which the fat resorption was impaired, the serum had low carotene and vitamin A values or vitamin A was lacking entirely. Patients with exophthalmic goiter showed extremely low carotene and vitamin A values or a complete absence of vitamin A. Following successful iodine therapy or after surgical treatment, the vitamin A content increased again. The highest carotene and vitamin A values were found in diabetes mellitus, and the fat content of the serum was found to be greatly increased. Insulin exerted no influence on the carotene and vitamin A contents. The carotene and vitamin A

contents of the serum were abnormal also in patients with pernicious anemia. After liver therapy the vitamin A content was found to increase in patients with pernicious anemia, however, this was not the case following administration of a liver extract. Medication with a vitamin A preparation did not produce a remission in pernicious anemia. There seemed to be no relation between pernicious anemia and vitamin A.

Erythremia with Migraine, Gout and Thrombophilia.—Weber reports a case presenting erythremia, migraine, gout and thrombophilia. In 1932 the patient passed through a condition resembling collapse, which lasted two days and had the aspects of a coronary thrombosis. He also complained of pains in the region of the spleen, which became considerably enlarged. The patient was under treatment for one year, but occasional venesections and a high fat diet produced no noticeable improvement in the erythremia. The gout improved under treatment. Months later at a new consultation, the patient stated that he had lived on a high fat diet and his condition was somewhat improved. However months later he had to be hospitalized, his general condition was poor and he had had tarry stools. Because of this symptom a duodenal ulcer was assumed and the suitable treatment was instituted but without avail, for the feces remained black. The patient died, and the necropsy revealed no ulcerations in esophagus stomach or duodenum. The hemorrhage must have originated in a strongly hyperemic portion of the ileum which must have been produced by a thrombotic or embolic infarct. The heart contained a number of thrombi. The spleen showed old infarct scars, and the splenic artery had an old thrombotic occlusion. The bone marrow was fatty in parts, but the largest portion was red and this portion contained only a few fat cells with a large number of megakaryocytes. The leukocytes were increased even more than the erythrocytes, and for this reason it seems justified to speak of erythroleukemia. The author is inclined to accept the neoplastic theory of the etiology of the leukemias and of erythroleukemia and calls attention to the shortcomings of Hitzenger's theory, according to which erythremia is caused by an overproduction of Castle principle in the stomach.

Functional Test of Liver F Oefelein—p 56

Action of Short Waves on Course of Brucella Abortus Infection—Izar and Moretti tried the short waves in treating nine cases of Brucella abortus infection. They used a tube apparatus of from 250 to 350 watts, which could be adjusted to wavelengths of from 4 to 8 meters and 15 meters. They employed only the 4 and 8 meter wavelengths. The organs treated were the spleen alone and the spleen and liver together. The treatments lasted from fifteen to twenty minutes and were repeated every day or at intervals of several days. The treatment always resulted in a reduction in the size of the spleen and liver and was always well tolerated. In some cases six or nine sessions resulted in complete cure, while in others the rays were applied from fifteen to more than twenty times. Six patients were completely cured and one was improved, but in two the results were still doubtful after a large number of treatments.

Experiments on Air Embolism—To determine what quantities of air entering the blood stream by intravenous injection are tolerated, Nemec injected into himself gradually, with an ordinary injection syringe, 2, 3, 4 and 5 cc. of air and did not observe the slightest symptoms. After two days he repeated the experiment by injecting at once rapidly 5 cc and by controlling his heart action with the phonendoscope. Again he observed neither subjective nor objective symptoms. This experiment with 5 cc. of air he repeated several times and always with the same negative results. Colleagues watched the experiments. The author also experimented with 10 cc. of air. At the first injection of this quantity he experienced

a slight restlessness and a feeling of oppression immediately following the injection. However, these sensations did not last more than ninety seconds. He thinks that they may have been the manifestation of a rudimentary embolism or of a nervous reaction. He cites observations made by Jedlicka on two horses given injections of large amounts of air and surviving the experiment. Later experiments were made on animals in a slaughterhouse. The animals were killed by opening of the carotid artery one hour after the air had been injected and it was observed that, as long as the heart action continued a foamy blood stream was discharged by the carotid and other arteries. The author concludes that an embolism resulting from a large amount of air does not need to terminate fatally as long as the cardiac action and defense movements of the body succeed in breaking up the air bubbles. This explains the favorable effect of artificial respiration (possibly in connection with oxygen inhalation) in accidental embolisms that develop in the course of an operation. Death caused by an embolism takes place instantaneously as the result of obstruction of the heart with a large air bubble, while small bubbles may pass through heart and lungs without severe symptoms. In the cerebral vessels they may cause disturbances after several hours. The quantities of air he tried on himself (5 and 10 cc.) are too small to permit general conclusions, but the repeated negative results indicate that under normal conditions quantities of 10 cc. or less are without danger.

Takata-Ara Reaction as Functional Test of Liver—Oselein cites three experiments that he conducted to clarify the action mechanism of the test. The experiments indicate that the positive outcome of the Takata-Ara reaction is largely determined by the ammonium ions. Since the liver is the site of detoxication of the blood ammonia, the amount of ammonium ions in the blood serum is an indicator of the functional capacity of the liver. He studied the ammonia content of the serum of patients with and without hepatic disorders so as to detect whether there is a parallelism between the ammonia content and the positive outcome of the Takata-Ara reaction. It was found that in all cases of positive Takata-Ara reaction the ammonia content of the blood serum was greatly increased and as a rule there was a parallelism between the degree of positivity of the reaction and the height of the ammonia content. The Takata-Ara reaction as a functional test is a specific indicator of parenchymal lesions of the liver.

- *Definition of Allergic Diseases L. Aschoff—p 1
- Clinical Experiences with Eugenic Sterilization A. Mayer—p 3
- Law for Prevention of Defective Offspring. Matzner—p 8
- Therapy of Chronic Hypokinetic Constipation in Older Persons N. Ortner—p 15

Allergic Diseases—Aschoff says that the term allergic should be restricted to disorders that appear in attacks on the basis of a hypersensitivity of the tissues. He deplores that at present there is a tendency to extend the term allergic by transferring the observations on the artificial allergy in animals to human subjects. This has gone so far that the allergic conditions that become manifest in the course of infectious diseases are made the center point in the discussion of allergic conditions. Instead of speaking of an allergy in infectious diseases or of an allergizing effect of infectious diseases, the process is considered apart from the infection as an allergic disease. This can be said especially of tuberculosis, which has been designated the prototype of allergic diseases. A disturbing confusion has been produced in that etiologically different and only symptomatologically somewhat similar disturbances are designated as allergic diseases because certain local histologic changes have a resemblance to the allergic inflammations that are produced artificially in animals. This applies for instance to the fibrinoid swellings of the connective tissue observed in physical and chemical injuries or in infectious processes. Since these fibrinoid swellings of the connective tissue are especially frequent in the artificially produced allergic inflammations, their appearance in human beings is interpreted as indicative of the fact that allergic factors are involved, and the entire disorder irrespective of its etiology is designated as an allergic disease.

A clinical symptom, such as the rheumatic one, which may be produced by widely different causes, has been identified with definite histologic changes, so that even if there is no clinical sign of rheumatism the term rheumatic or allergic is applied wherever a fibrinoid degeneration of the connective tissue exists. The author considers it necessary to raise objections to this disregard of all specific pathogenic and pathologic laws. He points out that the knowledge of the many different etiologically different diseases only because they have the same symptom namely pain advancing from joint to joint. From these points of view he criticizes Loewenstein's theory of the tuberculous etiology of rheumatism and also the attitude of Klinge, Roessle and Gerlach, who announce their departure from Virchow's cellular and organic pathology and oppose to this analytic method their own synthetic approach. The author considers this a step backward. He emphasizes that only a sharp etiologic differentiation makes an effective causal therapy possible and that the indiscriminate grouping together of syphilitic, tuberculous, rheumatic and atherosclerotic disorders under the heading of allergic disorders makes an effective therapy impossible.

- Studies on Development of Musculature in Children of School Age. A. Ruotsalainen—p 67

Anemia Neonatorum—Noll gives the history of a newborn infant having great pallor and a large spleen. The infant recovered without special treatment and during the existence of these symptoms it apparently felt well. The blood picture was characterized by a great reduction in the erythrocytes and in the hemoglobin content, by a flooding out of nucleated erythrocytes and of primary cells (that is, immature elements) and by the appearance of myeloblasts and myelocytes. There were poikilocytosis and anisocytosis and a hemoglobin deficiency in the cells. The color index was somewhat below 1. The family anamnesis gives no indications that would help to clarify the origin of this type of anemia. In this case the mother stated that at the end of her pregnancy she had had influenza and a severe cough. In another case the preceding child in the family had icterus gravis, and in still another a number of abortions and premature births had preceded the birth of the infant with anemia. The course of anemia neonatorum is usually favorable. The symptoms generally disappear between the second and the seventh month of life. Blood transfusions and iron and arsenic medication have been employed in other cases. In regard to the etiology of anemia neonatorum, various theories have been advanced. Ecklin assumed the diaplacental transmission of a virus or a toxin as the cause. Other authors discussed the possibility of an essential weakness of the hematopoietic system, and Grulee considered a close relationship between anemia neonatorum and erythroblastosis. In this connection the author points out that the blood picture as well as certain symptoms are similar in anemia neonatorum, congenital dropsy and icterus gravis neonatorum. For this reason it has been assumed that these three disorders are manifestations of the same blood disease, namely, an erythroblastosis. However even if anemia neonatorum is classified with the erythroblastoses, its origin is still unknown, for the etiology of the erythroblastoses has not been explained.

Symmetrical Parietal Fenestrations—Zarß shows that the term foramina parietalia permagna is erroneously applied to the abnormally large parietal openings for he maintains that they are not identical with the small parietal foramina known in normal anatomy. He demonstrates that the large parietal openings are the manifestations of developmental deficiencies and that they nearly always concur with other developmental disturbances and are an indication of anomalies in the ossification of the cranium. He describes a case of his own

observation, in which it was possible to observe the abnormally large parietal openings continuously from birth onward in a child with a microcephalic tower head and an extremely large accessory fontanel. He thinks that these abnormally large parietal openings should be designated as symmetrical parietal fenestrations.

Diagnosis of Pregnancy by Histidine in Urine—Brandsch employed the histidine reaction suggested by Kapeller-Adler on the urines of 121 women who had not completed their first half of the pregnancy period of fifty-six women who had advanced beyond that stage of eight women who had an abortion in the second or third month of pregnancy, of two women with tubal pregnancy, and on 120 specimens of urine from nonpregnant women. During the early stages of pregnancy the histidine test is not sufficiently reliable to permit the diagnosis of pregnancy for he obtained 19 per cent of negative results. In the women who were in an advanced stage of pregnancy the incorrect results amounted to 9 per cent and in the nonpregnant women to 10 per cent. The author concedes however that the urine of a large percentage of pregnant women contains histidine while this can be said of only a small percentage of nonpregnant women. He considers this an interesting peculiarity of the metabolism during pregnancy. The test is not sufficiently exact to constitute a reliable basis for the diagnosis of pregnancy.

Onset of Labor Pains—Kirchhoff advances evidence which indicates that there is a relationship between cosmic manifestations and the onset of labor pains but he is unable to state whether this biologic manifestation and the atmospheric processes have a causal connection or whether both are parallel results of great cosmic processes. He points out that a number of other physiologic manifestations show a sinelike curve in the twenty-four hour period parallel to the atmospheric processes. However in most of these the curve is the reverse of that representing the onset of labor pains or the blood sugar where these show an elevation the others show a downward trend and vice versa so it is with temperature, blood pressure pulsation elimination of water and basal metabolism. They all adhere to the twenty-four hour rhythm even if a person has to work at night instead of in the daytime. The author points out that it is of course self evident that the cosmic influence is not the only determining factor in the onset of labor pains. All other necessary factors must have reached the point of maturity before the exogenic cosmic factor can exert its influence.

Hypertonic Salt Solution by Rectum—Genkin and Milyavskaya state that hypertonic solution of sodium chloride administered rectally is a prompt and effective remedy in treating motor disturbances of the intestine in the postoperative period. They administered an enema of 100 cc of a 15 per cent solution in cases of postoperative colic or meteorism when other measures failed and always obtained a prompt evacuation

of the intestine. The method is likewise valuable as an aid in differentiating between functional and mechanical ileus. Because of its efficacy, the authors prefer this method to intravenous introduction of solution of sodium chloride. They administered a 5 per cent solution of sodium chloride by the rectal drip method in cases of intestinal obstruction. The slow method of administration has the advantage of replenishing the organism with chlorides in addition to ridding the intestine of toxic material.

Swallowed Foreign Bodies—Perslow has collected 225 cases of swallowed foreign bodies treated in seven Swedish hospitals between 1910 and 1929. The material in which all kinds of objects are represented is classified into different groups each comprising objects of similar nature. He maintains that the majority of swallowed objects are evacuated spontaneously without causing the slightest trouble or discomfort. Such is the case with all rounded objects. Spontaneous evacuation may also be expected in the case of all objects pointed at one end such as pins, safety pins, drawing pins, nails and screws. Experience shows on the other hand, that objects pointed at both ends readily get stuck during the passage, giving rise to severe complications. The author advises that these cases be kept under careful observation in the hospital while the others may be kept under observation in the outpatient department. He maintains that roentgen examination is indispensable in order to obtain a close knowledge as to the true nature of the swallowed object. He warns against relying on the history. A large number of foreign bodies have been removed by operation (usually gastrotomy), although in the author's opinion there was never really any indication for it, since in most cases there were no symptoms of any ill effects. As a life saving measure, operation had to be undertaken in only a few cases. The reason for the early operations seems to have been distrust of spontaneous evacuation. The author describes three cases in which the foreign body stuck in the esophagus and in which extraction by esophagoscopy was out of the question. By means of a soft stomach tube he pushed the foreign body down in the stomach. This method was successful in each case. He describes four cases of foreign bodies stuck in the esophagus in which repeated attempts at extraction by esophagoscopy failed. In all these cases the foreign bodies were removed by laparotomy, the stomach being opened sufficiently to allow the whole hand to be introduced and the foreign body grasped by a long pair of forceps introduced through the cardia. This procedure would seem to be the safest method. The author concludes that cases of swallowed foreign bodies should in the majority of instances be treated expectantly with bulky foods, such as puree, and restriction of fluids. The passage of the foreign body should be followed by roentgen examinations. Should the object tend to remain in the stomach, the patient should be put to bed and lie on his right side. If the foreign body remains in the cecum, its onward passage is best furthered by raising the foot end of the bed. He warns against giving laxatives. There is no indication for operation until intestinal symptoms or those of peritonitis appear, or until repeated roentgen examinations have proved the body to be impacted, but operation should be immediately preceded by roentgen examination.

FEVER THERAPY FOR GONOCOCCIC INFECTIONS

ARTHUR U DESJARDINS, MD

LOUIS G STUHLER, MD

AND

WALTER C POPP, MD

ROCHESTER MINN

For generations, gonococcic urethritis has been treated mainly by irrigating, or by injecting into the urethra various chemical solutions that were thought to have an antiseptic or germicidal effect. The gamut of the so-called urethral germicides has been run from the old standbys potassium permanganate and the "nonirritating" silver proteins argyrol and protargol to another group of miracle workers, the aniline dyes, mercurochrome, gentian violet and acriflavine. Each group and each substance has had its more or less vociferous protagonists, but the use of such substances is now gradually diminishing. This is not to imply that all these different chemical substances do not have any therapeutic value, but only that at various times too much reliance has been placed on this or that compound or group of compounds.

There is no doubt that many patients with gonorrhea have been cured by such methods, but many other patients have not been cured or have been cured only after weeks or months of treatment. So true is this that one cannot help wondering whether the disease was cured as the result of the treatment or as the result of those internal factors which constitute the natural defense against infection. In any event it cannot be denied that, even at the present time, the treatment of gonorrhea is an uncertain affair.

BACTERICIDAL ACTION OF HEAT ON THE GONOCOCCUS

In the past, many observers have noted an inhibitory effect of high temperature on gonococcic infections. Thus, Finger, Ghon and Schlagenhauser¹ failed to induce urethritis by injecting gonococci into the urethra of a patient who already had a temperature of 39 or 40 C (102.2 or 104 F), whereas urethritis always developed when the organisms were injected into afebrile subjects. Guard² in 1894 had a patient with gonorrhea whose urethral infection subsided spontaneously after scarlet fever. Bogdan³ in 1893 cited a case

of gonorrhea in which the urethral discharge had spontaneously disappeared during an attack of pneumonia but recurred after the fever had subsided. Neisser and Scholtz⁴ always found it difficult to cultivate the gonococcus in cases in which patients had a fever. Luys⁵ in 1917 made a similar observation after a patient of his had had an attack of mumps during which the temperature had attained 40 C (104 F). Culver⁶ recorded a similar case in 1917 in which the urethral infection was cured after the patient had had a four-day bout of malaria with a temperature of 40.5 C (104.9 F). He claimed that a sudden rise of temperature to 39 C (102.2 F) was sufficient to destroy the gonococcus. However, the experience of others, such as Nobl⁷ and Nicoll,⁸ was different.

Bacteriologists have long known that *Neisseria gonorrhoeae* can best be isolated and cultivated at a temperature of 37 C (98.6 F), and that the organism does not grow so well at temperatures greater than 38 C (100.4 F). Steinschneider and Schäffer⁹ in 1895 noted that a temperature of from 40 to 41 C (104 to 105.8 F) for a few hours was sufficient to kill the gonococcus. Wertheim¹⁰ in 1900 claimed that the organism grows well at 40 C (104 F) and can even tolerate 42 C (107.6 F), but this claim has not been substantiated by other investigators. Santos¹¹ was able in 1913 to isolate gonococci from pus that had been subjected to a temperature of 45 C (113 F) for less than forty-five minutes or to a temperature of 50 C (122 F) for less than five minutes. Ungermann¹² on the other hand, found that some strains of gonococcus resisted 41 C (105.8 F) for ten hours and that a few strains even withstood 52 C (125.6 F) for seven hours. On heating the male urethra with diathermy, Boerner and Santos¹³ could not isolate the gonococcus after ten hours at 39 C (102.2 F), three hours at 41 C (105.8 F), and fifty-seven minutes at 41.7 C (107 F). Ylppö¹⁴ treated vulvovaginitis of a girl, aged 5 years,

by means of hot baths, beginning at a temperature of 39 C (102.2 F) and gradually increasing the temperature of the water to 41.5 C (106.7 F). After eight daily baths of one hour, Yippo could no longer isolate the gonococcus. Koch and Cohn¹⁵ in 1928 expressed the opinion that the gonococcus can more readily tolerate a high temperature when in vivo than when in vitro. This opinion rested on the fact that, during an acute infectious disease in man, the infection may resist a temperature of 40 C (104 F) for several days.

FEVER THERAPY BY MODERN METHODS

For a number of years artificial fever, induced by the injection of bacteria or protein substances, by general diathermy or by short wave radiations, the heating effect of which had been fortuitously discovered by Whitney, who also realized its possible therapeutic value, has been used to treat syphilis of the nervous system, chronic arthritis and certain other conditions. During the last few years also the value of this method in treating acute gonococcal arthritis has been made increasingly clear. The rapid relief from pain and subsidence of inflammation obtained by thorough heating of the affected joints themselves, without general elevation of body temperature is remarkable enough, but still more startling is the almost theatrical effect of increasing the general body temperature of such patients to between 41.1 C (106 F) and 41.7 C (107 F) and maintaining it at this level for five or more hours.

Quite naturally observations of this kind led a few physicians to consider the possible value of such a procedure in gonococcal infections of the urethra and its associated structures. This possibility was brought into the realm of probability by the fundamental experiments of Carpenter, Boak, Mucci and Warren.¹⁶ These investigators undertook the task of determining the thermal death time of the gonococcus at temperatures that can be tolerated by man. They subjected fifteen strains of *Neisseria gonorrhoeae* to temperatures of 39, 40, 41, 41.5 and 42 C (102.2, 104, 105.8, 106.7 and 107.6 F). The different strains had been under cultivation from one month to twelve years. The resistance to fever of the different strains was found to vary, cultures that had been isolated ten and twelve years previously tolerated heat for a longer time than recently isolated cultures. Nevertheless it was found that at a temperature of 41 C (105.8 F) 99 per cent of the gonococci were destroyed in from four to five hours, but to destroy the remaining 1 per cent required heating at this temperature for from eleven to twenty-three hours.

When subjected to a temperature of 41.5 C (106.7 F) and 42 C (107.6 F), 99 per cent of the gonococci were killed in two hours whereas the remaining 1 per cent required heating from seven to twenty hours at 41.5 C or from five to fifteen hours at 42 C. From these results, Carpenter, Boak, Mucci and Warren concluded that artificial fever might be a valuable aid in the treatment of gonococcal infections.

RESULTS OF TREATMENT

Stimulated by the work of Carpenter, Boak, Mucci and Warren, and by the unpublished observations of Simpson we undertook to test the method in cases of

gonorrhea, both acute and chronic, with or without complicating lesions. Between December 1933 and September 1934 we have undertaken to treat by this method thirty-three patients with gonococcal infections of the genito-urinary tract, that is to say, thirty-three patients were referred for fever therapy. Of these thirty-three patients, four received only one session of treatment and either they did not reappear for treatment or the idea of treating them had to be abandoned for lack of cooperation, these four patients must be excluded from further consideration.

Of the remaining twenty-nine patients, twenty-five completed the treatment and were cured. By cure we mean precisely what is implied by the word cure: complete cessation of urethral discharge, disappearance of symptoms and of gonococci, in spite of repeated examinations.¹⁷ Moreover, these patients have remained free from discharge, symptoms and gonococci for from one to several months depending on how recently their treatment was completed. Ten of these patients (nine men and one woman) had a complicating acute gonococcal arthritis and the arthritis also was cured.

In nine of these twenty-five cases the urethral discharge ceased and smears were free from gonococci after the first session of treatment. In four cases the urethral discharge ceased and smears were free from gonococci after the second session of treatment. In three cases the urethral discharge ceased and smears were free from gonococci after the third session of treatment. In two cases the urethral discharge ceased and smears were free from gonococci after the fourth session of treatment. In four cases the urethral discharge and smears were free from gonococci after the fifth session of treatment. In two cases the urethral discharge did not cease and smears did not become negative until the patients had received seven and ten sessions of treatment, respectively. This fact will be commented on later. In one of the twenty-five cases the patient received eight sessions of treatment and was cured, but it is not certain how many sessions he received before the smears became negative.

Of the twenty-nine patients who can be said to have received systematic treatment, four were not cured. One was a woman aged 18, with acute urethritis. The second was a woman who had a relatively chronic urethritis, with cervicitis, salpingitis, and an acute gonococcal arthritis of the right knee. The third and fourth patients were girls, aged 5 and 8 years, respectively, who had acute gonococcal vaginitis. At the time the first two patients were treated, the only fever chamber available was not air tight, and great difficulty was experienced in inducing a sufficiently high temperature and in maintaining the fever long enough to be effective. Moreover, one of these patients (the first named) did not tolerate the treatment well. Her pulse rate was flighty, and nausea and vomiting supervened at each session of treatment. This relatively unusual complication greatly increased the difficulty of treatment. As for the young girls with acute vaginitis, the condition of both improved, the discharge did not cease completely, however, although each received eight sessions of fever. It is true that, during some sessions, it was impossible to maintain the temperature consistently above 41.1 C (106 F), and the early sessions were far from satisfactory. This may have had a great deal to do with our failure to cure these patients with fever alone.

17 In all cases smears were made and examined each day except on days that the patients were treated.

From the foregoing it may be seen that all the male patients who cooperated faithfully were cured, whereas for the female patients a cure appears to have been more difficult to obtain. As has been explained, much of this difficulty arose from imperfect insulation of the first fever chamber, with which most of the female patients were treated, but this does not account altogether for the failure to cure all the female patients. With the improved chambers that we now have and with greater experience we are convinced that the cure of a large proportion of female patients can be obtained, we doubt, however, that the percentage of such patients who can be cured can ever attain 100. The nervous system of the average woman is less stable than that of the average man. Probably related to this circumstance is the relative instability of the gastro-intestinal tract of the average woman. The skin of the average woman also is more sensitive, moreover, secondary infection is more common than among men. All these factors tend to make treatment more difficult and less effective.

In spite of these difficulties, however, there is no doubt that a large majority of female patients who have gonococcal infections can be cured by this method in much less time than by the methods heretofore in vogue.

As an example of the possibilities, the following may be of some interest. One day, one of us received a visit from a physician who was accompanied by another man. The physician told the following story. A few weeks previously, the wife of the man who accompanied him had noticed a vaginal discharge which she could not understand and she asked the physician about it, but, not even thinking of the possibility of gonococcal infection, he told her that the discharge was not significant and would probably subside spontaneously. Both husband and wife had always been healthy and had lived regularly. About a week later she again mentioned the subject to the physician, who again regarded the matter as insignificant and did not even trouble to examine the discharge.

A short time afterward, the husband presented himself to the physician and complained of a urethral discharge, smears of which contained an abundance of gonococci. The physician then proceeded to examine smears taken from the wife, and these also contained innumerable gonococci, moreover, on examination, left-sided salpingitis was found. All factors of a clear history indicated that the infection of both patients had been innocently acquired.

Having heard that another patient from the same locality had been cured by the fever method, the physician had come to inquire about it on behalf of his companion and of the companion's wife. They were told that promises of cure could not be made but that previous experience encouraged us to believe that a cure might be possible, whereupon it was decided that the husband would be treated first and, if the treatment should prove successful, his wife could then be given the benefit of the same procedure. Briefly, the husband's urethritis was cured after four sessions of fever. Then the wife, who already had a complicating salpingitis on the left side, also submitted to treatment. Owing to an unusually sensitive skin, a sufficiently high temperature could not be attained during the two initial sessions of fever. After this the skin tolerated a satisfactory degree of temperature, and four additional sessions of treatment were sufficient to cure not only

the urethritis but also the salpingitis. Both husband and wife have been perfectly well since then.

TECHNICAL CONSIDERATIONS

How do patients tolerate such treatment? In treating gonococcal infections, the aim is to destroy the infecting organism directly by subjecting it to a sufficiently high temperature for a sufficient length of time. At the outset, it was arbitrarily decided to raise the temperature to between 41.1 C (106 F) and 41.7 C (107 F) and to maintain it at this level for five consecutive hours. On the average it requires from sixty to ninety minutes, and in some cases even longer, to bring a patient's temperature to 41 C (105.8 F), and at the end of a session of fever at this level it requires approximately the same length of time for the temperature to return to normal. The temperature of many patients could be raised more rapidly, but to push the fever too rapidly would be to strain the power of the skin to adapt itself and might result in burns, which should and usually can be avoided. The majority of patients tolerate treatment quite well and the way patients behave under treatment is an absolute function of the character and temperament of the individual. Persons who are determined to get well as quickly as possible take their sessions of fever without a whimper, some even sing (not from delirium but to while away the time) and smoke during each session. Others begin to ask to be released from the chamber long before the treatment session has been completed. Naturally, five hours at a temperature of from 41.1 C (106 F) to 41.7 C (107 F) or even a little higher is not only a fairly strenuous cardiovascular functional test but also a thorough test of the character of an individual. Pampered persons, without intestinal fortitude, or persons who do not understand the meaning of self restraint, are bad subjects for fever therapy, and their failure to cooperate often makes effective treatment difficult or impossible.

At first also the treatment sessions were repeated, in cases in which the urethral discharge had ceased after the first session, only when the discharge reappeared. Moreover, when the discharge did not disappear after the first or after subsequent sessions, several days (from three to seven) was then allowed to intervene between sessions. As experience soon showed, it was unwise to allow so many days to elapse between the sessions of fever. Since then we have modified this procedure, and now only two days is allowed to intervene between the different sessions of treatment. In this way, whenever the discharge ceases, whether this is after the first, second or any subsequent session of treatment, it usually does not reappear.

If patients could be treated every day instead of every second or third day, the disease could be cured more rapidly and with even greater certainty, but this is hardly feasible. A temperature of from 41.1 C (106 F) to 41.7 C (107 F) maintained for from five to six or eight hours taxes the strength of the average individual to a considerable degree. If measures to prevent it were not taken, considerable loss of weight and strength would occur and would probably continue for some days. The loss of weight would result from loss of fluids by perspiration, and the loss of strength would result chiefly from loss of chlorides. This difficulty is largely obviated by causing the patients to drink, during each session of treatment, from 2 to 5 liters of a 0.6 per cent solution of sodium chloride. As a result of this procedure, the weight of the average

patient actually increases during a treatment session, and the incidental fatigue, instead of continuing for days, usually disappears in from twelve to twenty-four hours. To minimize the fatigue further and to make the long sessions more bearable, especially for nervous and apprehensive patients, sedatives are given from time to time. Of these we have found codeine, pentobarbital sodium (nembutal) and sodium amytal the most satisfactory. Dilaudid is not reliable and may give rise to unnecessary complications. Morphine is to be avoided because of its tendency to induce nausea and sometimes vomiting, which may considerably interfere with treatment.

Another significant feature of the treatment as applied in this series of cases was that three patients had to be subjected to seven, ten and twelve sessions of fever, respectively, before the gonococcal infection was cured. This was attributable to two factors: the temperature and the time during which it was maintained. In these particular cases either the temperature was not raised sufficiently or the time during which the fever was maintained was too short, usually the two factors combined to diminish the effectiveness of treatment. In gonococcal infections there is no doubt that the therapeutic efficacy of fever is absolutely a function of the degree of temperature attained and of the time during which an adequate degree of temperature is maintained. Patients vary considerably in the readiness with which their temperature can be elevated and, as a corollary, the temperature of some patients can be raised to any desired degree in much less time than that of other patients whose mechanism of temperature control is much less labile or more resistant to external influences.

When these three patients were treated the treatment was supervised by a medical assistant who was obliged to work in another service during the latter part of the afternoon. Therefore if the temperature of a patient was slow to rise this was not compensated for by extending the total duration of the session, the patients were withdrawn from the fever chamber at a fixed time, regardless of the period during which a temperature between 41.1 C (106 F) and 41.7 C (107 F) had been maintained. In these particular cases, for the reason given, such a temperature was not maintained for five hours but only for four or even three hours. This is why so many more sessions were required to effect a cure.

This experience caused us to modify the scheme of treatment as it relates to the time factor, which is quite as important as the temperature factor. The present scheme of treatment is to raise the patient's temperature to 41.1 C (106 F) and to maintain it between 41.1 C (106 F) and 41.7 C (107 F) for six hours at each of the two initial sessions of treatment which are regarded as test sessions. If by this time the urethral discharge has ceased and gonococci have disappeared from smears, one or two additional sessions of fever are given in order to prevent any possibility of recurrence. If the discharge has not ceased after the second session of treatment, however, the subsequent sessions are extended to seven or eight hours during which a temperature between 41.1 C (106 F) and 41.7 C (107 F) is maintained as steadily as possible. With this scheme of treatment, more than four sessions should seldom be required to effect a cure.

Of course, an individual who, either because the skin is exceptionally sensitive or because there is a strong natural resistance to fever, cannot be brought to the

required degree of temperature, or whose temperature cannot be maintained at this level for a sufficient time, may occasionally be encountered. If, in such cases, the same tendency manifests itself at each of three or four consecutive sessions, a cure will probably not be obtained. Naturally, this depends on the degree of discrepancy between the required maximal temperature and the temperature actually attained and maintained. Such cases fortunately, are quite exceptional. Not infrequently, at the first session or two, there may be some difficulty in raising the patient's temperature to the proper level. When this is the result of sensitiveness of the skin and an abnormal tendency to local erythema (from excessive accumulation of heat in an area in which the circulation or the distribution of sweat glands may be deficient) the difficulty can generally be overcome by cooling this area with ice or covering it with a bandage. But when the difficulty is the result of a tendency to diffuse erythema from an extensive functional inefficiency of the sudoriferous system, the problem may solve itself. One or two sessions of moderate fever may so increase the functional capacity of the perspiratory mechanism that more effective treatment may subsequently become feasible.

As for the ten cases in which urethritis was complicated by gonococcal arthritis, the inflammatory process subsided quite rapidly. Moreover, the articular inflammation in these cases has not recurred for weeks or months since the patients were treated.

The temperatures mentioned throughout this paper represent rectal temperatures.

As long as the patient's rectal temperature remains below 40 C (104 F) the temperature is taken every ten or fifteen minutes, but after the temperature has risen above this level it is taken and recorded every five minutes. Sufficiently accurate recording thermometers have not yet become available, and we have insisted throughout on the careful use of a hand thermometer. This has one important advantage. Recording mechanical thermometers are quite impressive for visitors, but a functional failure might prove disastrous. Moreover, when a nurse is given a dial to watch and is instructed to govern her actions by its indications, her natural tendency is to give her attention to the dial rather than to the patient. We feel therefore, that the hand method of taking the rectal temperature has advantages which should not be lightly cast aside.

APPARATUS

The treatment in the cases reported has been carried out by means of the air-conditioned fever chamber known as the "Kettering hypertherm," the development of which has been the result of the collaboration of Dr. Walter M. Simpson of the Miami Valley Hospital, Dayton, Ohio, and of Mr. C. F. Kettering, director of the Division of Research, General Motors Corporation also of Dayton.¹⁸ The chamber consists of a horizontal box, the base or bed of which can be rolled in or out at will. The patient lies on this bed, resting on a comfortable air mattress which is rolled into the chamber proper, and the chamber is then hermetically closed by means of a sliding vertical panel, through which the head of the patient projects. Thus, when the chamber is closed, the patient's body is within the chamber while the head is outside, resting on a shelf provided for the purpose. At the foot of the chamber, in a special compartment, is the simple machinery that heats and

¹⁸ We are indebted to Dr. Simpson and Mr. Kettering for their kindness in placing these fever chambers at our disposal.

humidifies the air. The temperature of the air within the chamber is controlled by a thermostat and can be varied at will. The relative humidity of the air is controlled by a humidistat, and this factor also can be increased or decreased as may be required. By means of a fan the heated and humidified air is forced between the two layers of the double ceiling of the chamber, down over the patient, and thence back to the special compartment at the foot end of the chamber, through a metal grill in the partition which separates the patient from the mechanism. The column of heated and humidified air is thus made to circulate around the patient about ten times a minute. The patient's body is entirely free within the chamber, and no electrodes or other electrical gadgets of any kind come in contact with the patient at any time. This is one of the chief advantages of this method of fever therapy over any method that involves diathermy or short-wave radiations with their electrodes or condenser plates. Another important advantage is the facility with which the patient's skin can be examined, the rectal temperature taken and all the physical needs of the patient attended to, throughout a session of treatment. This is made possible by sliding panels on each side of the chamber; these can be opened at any time for the supervising physician to examine the patient's skin or for the specially trained nurse to take the patient's temperature, to change the single blanket that covers the patient when it becomes soaked with perspiration, for the introduction of a bed pan, or for any other purpose. Also, in case of emergency, the chamber can be thrown open and the patient withdrawn in a few seconds.

CONTRAINDICATIONS

In the past advanced age, cardiac and renal disturbances, arteriosclerosis, pulmonary tuberculosis and diabetes have repeatedly been mentioned as formal contraindications to fever therapy in general. There is no doubt that old age, organic lesions of heart and kidneys and arteriosclerosis greatly increase the risk of fever therapy. As for pulmonary tuberculosis and tuberculous lesions generally, there are reasons for believing that, in selected cases at least, fever therapy may indeed prove a valuable therapeutic procedure. This possibility is now being investigated.

Wilder and others have demonstrated that well controlled diabetes does not preclude even major surgical procedures. For this reason, Wilder felt that diabetes, if under satisfactory clinical control, should not bar a patient from fever therapy if this should otherwise be indicated. Having under his care a man with diabetes who had recently acquired a gonorrheal urethritis, and the diabetes having been under control for some time, Wilder referred him for fever therapy. Needless to say, other contraindicating factors did not exist. After the first session of fever the patient had a reactive flurry, but this subsided rapidly. On the whole, he tolerated the treatment just as well as any other patient and the gonococcal infection was cured. The discharge did not cease and smears continued to show gonococci until after the seventh session of treatment. This was because, at each of the early sessions, the required degree of fever was not maintained long enough; the patient was withdrawn from the chamber after only four hours of maximal fever. If this could have been avoided, and if, from the very start, the required temperature had been maintained for at least five, and preferably six, hours, it is certain that the number of sessions could have been materially reduced. This case

is not described in greater detail because Wilder intends to make a complete report of it. It is mentioned here only to bring out the fact that diabetes need not bar a patient from fever therapy, but it is essential that the diabetic manifestations should be under good clinical control and that the patient should be free from other complicating disturbances.

COMMENT

Treatment of this kind requires the constant attention of nurse technicians, who must be carefully selected and specially trained. Just as important, however, such treatment must have the constant supervision of a physician familiar with all the details of the method. By constant attention on the part of the nurse we mean that she must not leave the patient for an instant as long as the patient is in the chamber. If she must absent herself momentarily, her place must be taken by another technician or by the supervising physician. The nurse technicians and the physician on service are not allowed to go out to lunch; lunch is brought to them and is eaten in the service. If fever therapy is conducted in this way, and if the patients subjected to such treatment are carefully selected, only minor complications need be anticipated. Such minor complications include herpetic lesions around the lips and mouth, occasional blisters in skins that are unusually sensitive and that are slow to adapt themselves to a rapid rise in temperature, and muscular tetany, usually limited to the hands and feet but which may sometimes (as in one of our cases) affect the abdominal muscles. This is an uncommon disturbance, is apparently the result of overventilation and disappears almost instantly on administration of carbon dioxide and oxygen, it often abates just as promptly on intravenous injection of 10 cc of calcium gluconate.

Fever therapy, especially for conditions that require such high temperatures, should preferably be conducted in an institution where the work can be properly organized. There is no reason why any well trained physician could not undertake such treatment. But for a physician to think that he can turn a button in the morning and leave the patient to the tender mercies of a technician, while he goes down town to call on other patients and attend to his usual practice, would be a dangerous fallacy. In most cases perhaps nothing serious would happen, but the physician would never know when, on returning, he would have to face a major calamity, the responsibility for which would rest on him and not on the technician.

SUMMARY AND CONCLUSIONS

Between December 1933 and September 1934, thirty-three patients suffering from simple urethritis or from urethritis complicated by cervicitis, salpingitis or arthritis were referred for fever therapy. Four cases must be excluded because the patients did not return after the first session of fever or because they failed to cooperate and the idea of treating them had to be abandoned.

Of the twenty-nine remaining patients, twenty-five received systematic treatment and were cured.

The average number of sessions of fever required to effect a cure was 5.4. The largest number of sessions required was twelve in one case, this was owing to the fact that, during the early sessions, an adequate degree of fever was not attained or was not maintained long enough. The lowest number of sessions of fever required for cure in any case was three.

Four patients were not cured, probably because the required degree of temperature could not be attained or consistently maintained for a sufficient time

During the early phase of this work the sessions of fever were repeated only when the urethral discharge reappeared, that is, after a lapse of from three to seven days. Later, only two days was allowed to intervene between sessions

At first also a rectal temperature between 41.1 C (106 F) and 41.7 C (107 F) was maintained for five hours in most cases, but in some cases such a degree of fever was not attained or it was not consistently maintained for five hours. This explains why a few patients required as many as seven, ten and in one case even twelve sessions of fever to effect a cure

Now, the first two sessions are regarded as test sessions, and a temperature between 41.1 C (106 F) and 41.7 C (107 F) is maintained for six hours. If by that time the urethral discharge continues and gonococci are still found in smears, the duration of subsequent sessions is increased to seven or eight hours. With such a scheme of treatment, more than four sessions of treatment should seldom be required

The case of a husband and wife, both suffering from gonococcal urethritis, the wife having a complicating unilateral salpingitis, and both husband and wife being cured after four and six sessions of fever, respectively, illustrates the possibilities of the method

Well controlled diabetes does not contraindicate fever therapy for gonococcal infection or for any other condition for which fever therapy may be indicated. The case of a man who had diabetes, and who was cured by fever therapy, substantiates this conclusion

When fever therapy is properly carried out, with specially trained nurse technicians in constant attendance, with the constant supervision of a physician familiar with all phases of such treatment, and when the cases are carefully selected, only minor complications need be anticipated. These include herpes labialis, an occasional skin blister, and muscular tetany (hands, feet and sometimes the abdomen), which promptly disappears on administration of carbon dioxide and oxygen or on intravenous injection of calcium gluconate

As sedatives, codeine, pentobarbital sodium and sodium amytal have been found most satisfactory. Dilaudid is unreliable and may lead to collapse. Morphine should be avoided because of its tendency to induce nausea and sometimes vomiting, which may seriously interfere with an adequate intake of fluids and chloride during treatment

Fever therapy, especially for conditions requiring a high temperature, should be conducted in an institution where adequate facilities and trained personnel are available. It cannot be carried out in conjunction with other medical practice without increased risk

The Heating of Tomato Juice—In very careful experiments made by the late Dr. Grose it was found that four hours heating of tomato juice of natural acidity involved a destruction of 20 per cent of its vitamin B at 100 C. (212 F), 33 per cent at 110 C. (230 F), 47 per cent at 120 C. (248 F), 55 per cent at 130 C. (266 F). Thus there is no sudden destruction or suddenly accelerated rate of destruction at any particular point, but rather, like most chemical reactions, the reaction by which vitamin B is destroyed under such circumstances runs at a rate which increases gradually with increasing temperature. There may of course be further losses if the food is cooked in water (or canned) and the cooking water (or liquid in can) rejected—Sherman, H. C. Food and Health, New York: Macmillan Company, 1934

STUDIES OF VELOCITY AND THE RESPONSE TO INTRAVENOUS INJECTIONS

V THE APPLICATION OF THE INTRAVENOUS DRIP METHOD TO CHEMOTHERAPY AS ILLUSTRATED BY MASSIVE DOSES OF ARSPHENAMINE IN THE TREATMENT OF EARLY SYPHILIS

LOUIS CHARGIN, M.D.

WILLIAM LEIFER, M.D.

AND

HAROLD THOMAS HYMAN, M.D.

NEW YORK

In chemotherapy the optimum therapeutic result is obtained by the introduction of the specific agent in quantities that suffice to destroy the noxious invader without seriously or permanently injuring the cells of the host. Under controlled conditions, this ideal is approached in animals that have been experimentally infected with syphilis and then promptly and adequately treated with arsphenamine.¹ In human syphilis the problem offers greater difficulties: treatment is delayed, the dosage must be augmented, idiosyncrasies are encountered, there occur technical errors in the administration of the drug, and untoward reactions may follow varying from mild and transitory disturbances to fatal poisoning

In a previous communication, one of us (Hyman) demonstrated that the "rapid intravenous introduction of pharmacologically active or inert chemicals, drugs and biologic fluids may give rise to alarming and, at times, fatal symptoms"—a syndrome which was termed "speed shock." It was further shown that the "slow intravenous introduction of these same agents and even highly toxic substances (anaphylatoxin, histamine) could be accomplished with impunity by means of the intravenous drip." These results made it necessary to reinvestigate the specific toxicity of many substances. If untoward reactions, in part at least, were technical and hence preventable, potent therapeutic agents might be administered, by means of the intravenous drip, in doses far greater than at present employed, and thus without serious damage to the cells of the host. The present study deals with such an investigation, as suggested by Chargin, and it has for its purpose an intravenous drip of massive doses of arsphenamine in the treatment of early syphilis, approximating the ideal of a "sterilisation magna."²

TECHNIC

The drip was set up in the manner previously described.⁴ Dextrose in 5 per cent solution was administered by the usual gravity method at a rate of 100 cc

This work was made possible through the generosity of the trustees of the Mount Sinai Hospital and a special gift from Mr. Ernst Rosenfeld. Read before the Section on Dermatology and Syphilology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

per hour. At the end of the hour there was added a solution of 0.1 Gm of neoarsphenamine dissolved in 50 cc. of 5 per cent dextrose solution. During the succeeding hour the dextrose was given again and this in turn was followed by the arsphenamine until the total daily dosage had been administered. Thus in a period of fifteen hours a patient might receive 1,500 cc of 5 per cent dextrose and 1 Gm of neoarsphenamine. The treatment was usually started at 8 or 9 a. m. and was continued throughout the day, the needle remaining *in situ*. The patients were kept in bed. A semisolid diet, rich in carbohydrates, was ordered and this, together with the intravenous dextrose, served to protect the liver from damage by the arsenic.

CHOICE OF MATERIAL

Only male patients in good physical condition were chosen for this study, and all were suffering from early syphilis. One patient presented himself in the seronegative primary stage, while the remainder had infections not older than three months. Consequently the clinical manifestations were limited to the chancre or secondary eruptions or both.

MASSIVE DOSAGE OF NEOARSPHENAMINE IN THE TREATMENT OF EARLY SYPHILIS

The twenty-five patients on whom we shall report received almost 100 Gm of neoarsphenamine, or an average of 4 Gm per patient (table 1). This dosage was usually administered over a period of five days. The daily dosage averaged 0.8 Gm of neoarsphenamine or 160 mg of arsenic. In the majority of instances 0.5 Gm was administered on the first day in order to test out the reaction of the patient to the drug. On succeeding days the usual dose was 1 Gm, but in some instances in which for technical reasons the drip was removed, a lesser amount was given. In a few instances (case 16) as much as 1.3 Gm was administered daily.

The use of the so-called massive doses of arsenic, especially in the treatment of early syphilis, had long since been employed by Scholtz,⁵ Pollitzer,⁶ and more recently by Schreus.

Scholtz⁵ administered, in divided doses, over a period of twenty-four hours, a total dosage of from 0.85 to 10 Gm. These injections were given at 8 a. m. and 2 p. m. of the first day and at 8 a. m. the following morning. Pollitzer⁶ administered, on three successive mornings, daily doses calculated on the basis of body weight, giving approximately 0.1 Gm of arsphenamine for each 25 to 30 pounds (11.3 to 13.6 Kg) of body weight. The total dose would accordingly vary between 1.2 and 1.35 Gm. Schreus⁷ and Bernstein gave a total of from 1.2 to 1.5 Gm of neoarsphenamine in three injections in a single day and repeated this dosage every week for five or six weeks until a total amount of from 6 to 9 Gm was administered.

In average therapy the single dose of neoarsphenamine varies from 0.3 to 0.6 Gm (a minimum of 0.1 and a maximum of 0.9 Gm). This dosage is usually administered at intervals of from five to seven days and ordinarily there are from eight to ten injections in a series, so that a total of approximately 5 Gm of neoarsphenamine or its equivalent given over a period of

from six weeks to three months constitutes an average course. By contrast, we endeavored to administer the entire amount of an average course over a period of a few days.

The Cooperative Clinical Group,⁸ by way of comparison, administers from 3 to 3.5 Gm of arsphenamine in the course of six weeks. They suggest from 0.3 to 0.6 Gm (0.1 Gm per twenty-five pounds of body weight) on the first, fifth and tenth days, and then 0.4 Gm at weekly intervals for four doses or until six weeks has elapsed. Our dosage given over a period of five to six days thus exceeds the amount that this group gives over a period of as many weeks.

From the standpoint of the cure of the syphilis, the advantages of the present scheme appear to be self evident. It affords an approach to Ehrlich's original conception of a sterilizatio magna, in that it makes possible the massing of the dose of arsphenamine at a time when it can exert its most potent action.

THE EFFECT OF MASSIVE THERAPY ON THE CLINICAL MANIFESTATIONS OF EARLY SYPHILIS

The effect of these massive doses on the clinical manifestations of the syphilitic infection was specific, as was to be expected. Chancres and secondary eruptions healed rapidly, those with markedly infiltrated lesions less rapidly than those less infiltrated. In most of the instances in which secondary eruptions were present a Herxheimer reaction became manifest about twenty-four hours after therapy was instituted, lasted until the following day, and then gradually faded out. Almost invariably there was an accompanying rise in temperature, varying between 101.5 and 104 F and reaching its height in twenty-four hours. It is of interest to observe and important to stress that in those cases in which no secondary eruption was present the temperature frequently rose exactly as in the other group of cases. This temperature rise may be regarded as a type of "Herxheimer" reaction.

EFFECT OF MASSIVE DOSES OF ARSPHENAMINE
ON SEROLOGIC TESTS

In a paper in 1921, Chargin⁹ expressed the view that the serology is the most valuable guide for determining the efficacy of any method of treatment in early syphilis. This dictum still holds true, and while seronegativity does not necessarily mean "cure," it is the most tangible yardstick that can be employed in any discussion of the efficacy of treatment in syphilis.

The serologic results in our twenty-five patients may be grouped in three categories. In the first group we include six patients (5, 10, 13, 22, 24 and 25), who were lost from observation before a change in the serologic reaction could be anticipated (table 2). One of these patients disappeared after the first week, one after the third week, one after the fourth week, two

patients. It is necessary also to comment on patient 15. In the seventeenth week, though he had no clinical manifestations of syphilis, his Wassermann reaction was 2 plus. We have included him in the seronegative group with this explanation. Subsequently, his test became negative also (table 2).

In his classic survey of the subject, Moore¹⁰ states that 52.6 per cent of the cases of early syphilis become seronegative on or before the end of the third month. The Cooperative Clinical Group,⁸ treating their seropositive primary and secondary cases with bismuth and mercury compounds as well as with arsenic, give, as average results, a seronegative serum in slightly more than 50 per cent and they state that the best results varied between 61 and 82 per cent. By way of comparison, and realizing the limitations of so small a

after the fifth week, and one after the ninth week. In all these instances the Wassermann reaction was still 4 plus.

The remaining nineteen patients were observed beyond the critical period of three months. These patients may be subdivided in the last two categories: the seropositive and the seronegative groups.

The seropositive group contains but one individual, patient 6, who was still positive in the sixteenth week. This man, who was one of the earlier in the series, received but 2.9 Gm of the drug.

The seronegative group includes eighteen of the group of nineteen patients who were followed for more than three months. The period for the clearing serologically averaged ten weeks. In two instances (cases 2 and 20) a negative test was not obtained for more than three months. Patient 20 was not seen between the second and the sixteenth week. Patient 2 received only 2.9 Gm of the drug, as he was one of the earlier

group, we cannot refrain from pointing out that eighteen of the nineteen patients that we followed, or slightly less than 95 per cent, attained seronegativity in a period averaging less than three months, though they received neither of the adjuvant heavy metals.

THE TOXICITY OF THE ARSPHENAMINE WHEN
ADMINISTERED BY THE MASSIVE METHOD

Pain in and about the site of injection was present at one time or another in every instance. The pain varied considerably in degree and duration. It was present in spite of the fact that no perivascular infiltration occurred in any of the cases. A mild and self-limited phlebitis occurred only three times. In only one instance was the pain sufficiently severe to demand the temporary discontinuance of the drip. Usually it was easily controlled by the administration of acetylsalicylic acid with or without codeine phosphate. As this type of pain occurs fairly frequently with drip therapy when

¹⁰ Moore, J. E. The Modern Treatment of Syphilis. Baltimore. Charles C. Thomas. 1933. p. 188, table 7.

dextrose alone or saline solution is used, it cannot be attributed to the arsenic employed

NITRITOID CRISIS

No instance of nitritoid reaction was recorded in this series, though it is the general experience that such reactions occur in from 1 to 2 per cent of all cases in which other methods of administration have been employed¹¹ This supports our earlier work² in which we stated our conviction that these nitritoid crises, as well as the so-called anaphylactoid phenomena were nonspecific and probably identical with 'speed shock'

FEBRILE REACTIONS

Temperature elevation occurred within the course of the first thirty-six hours in 80 per cent of the patients In five of those who had secondary skin eruptions a typical Herxheimer skin reaction also occurred reaching its height twenty-four hours after therapy The cutaneous reaction persisted until the following day The average temperature approximated 101.5 F, but in

SYSTEMIC REACTIONS

General systemic reactions were not very severe in character and necessitated temporary cessation of treatment in only a small number of instances Chief among these symptoms were headache, nausea and vomiting, which occurred in twelve (48 per cent) of the group Abdominal cramps occurred in eight (32 per cent) of the patients and varied in severity but were never sufficiently severe to require interruption of the treatment Among the other general symptoms observed were loss of appetite in two (8 per cent), chilliness in five (20 per cent), and marked sweating in four (16 per cent) Two of the patients, or 8 per cent, complained of inordinate weakness These symptoms are often enough encountered in all types of arsenotherapy

SKIN REACTION

The cutaneous by-effects, which were eight in number in our series, were remarkably mild in type They were entirely of the exanthematous variety, six being scarlatiniform in character, one urticarial and one morbilli-

Last urine specimen lost so determination is made on dosage up to this point

several instances it exceeded 103 The temperature elevation bore no relationship to the eruption, either in its extent or in its character Whenever the temperature rose beyond 101.5 F there were usually accompanying symptoms, such as malaise, nausea, vomiting and anorexia In such instances, treatment was temporarily suspended Usually within twelve hours after the cessation of drip therapy the temperature fell to normal, and treatment could be resumed without further interruption In only four instances was it necessary to lose a complete day of therapy

Secondary temperature reactions occurred in 68 per cent of the cases and these were markedly irregular both in extent and in the day of appearance as compared with the Herxheimer temperature The secondary temperature elevations approximated 102 though in one instance the temperature rose to 105.6 On interruption of treatment the temperature dropped to normal in a few hours, and only rarely was there any cause for alarm

Febrile reactions also occur in patients treated by the usual ambulatory methods

In five the eruption appeared at or immediately after the termination of treatment and in three while the patient was still under treatment In none did the eruption last longer than three days There was only slight itching and no desquamation In the three in which eruption developed while under treatment the injections were immediately stopped until the eruption disappeared In two of the latter the eruption reappeared when treatment was resumed, but again it was evanescent in character No eruption of the eczematoid variety was observed and no further skin outbreak of any type was seen during the period of observation, which in many cases is now longer than five months

CLINICAL EVIDENCES OF LIVER DAMAGE

Not a single instance of jaundice occurred either during treatment or during the ensuing period of observation Bile was never found in any urine specimen and the icteric index showed no elevation after completion of the course

POLYNEURITIS

Polyneuritis was observed in eight cases (32 per cent) It was moderately severe in two instances in which there were muscle pains and paresthesias in the

11 Schamberg J. F. and Wright C. S. Treatment of Syphilis New York D. Appleton & Co. 1932 p. 243

hands and feet, chiefly the latter. The symptoms appeared after the termination of treatment, usually within a few days, and persisted in the two severe cases for a period of six weeks. The condition was less marked in the other six cases and consisted chiefly of paresthesias, much milder in character and lasting less than three weeks. No relationship existed between the onset of polyneuritis and the quantitative arsenic elimination in the urine of these patients (table 3).

Because polyneuritis is more frequently associated with neoarsphenamine, we plan to employ arsphenamine in a future study.

LATE PARENCHYMATOUS DEGENERATION

The most dreaded complications of arsenotherapy are the severe late intoxications, including the eczematoid and exfoliative dermatitides, parenchymatous degeneration of the liver and kidneys and peripheral polyneuritis of a severe and lasting nature. To date we have not encountered a single instance of any of these untoward manifestations.

THE URINARY EXCRETION OF ARSENIC

Under the direction of Dr. Sobotka of the Chemistry Laboratories of the Mount Sinai Hospital, Dr. Leifer studied the urinary excretion of arsenic in all our patients. The chemical procedure used was a slight modification of the Green¹² iodometric microtitration. It would have been highly important to study the fecal excretion as well, but time did not permit.

Estimating that neoarsphenamine contains 20 per cent of arsenic, we concluded that the average urinary excretion was 21.1 per cent. The results varied between 10.6 and 37.2 per cent. In only two instances did the total elimination fall below 15 per cent (table 3).

The main channel of excretion of arsenic is unquestionably the feces. Mathieu¹³ found that the fecal arsenic excretion was approximately 2.5 times that of the urine. Clausen and Jeans¹⁴ reported it to be five times as great, and Underhill and Davis¹⁵ showed that the fecal elimination is considerably higher than the urinary excretion.

The figures of urinary excretion alone, consequently, serve only as an index, and the average figure of 21.1 per cent may be taken to mean only that the total elimination was probably proceeding satisfactorily in amount and rate.

There was no apparent relationship between the amount of urine excreted and its arsenic content. In no instance did there occur any suppression of or interference with urinary function. The daily urine specimens showed no renal irritation of any consequence except for the occasional and transitory presence of minor traces of albumin. In many instances the urinary output was voluminous, reaching from 5,000 to 6,000 cc in twenty-four hours, probably because of the diuretic action of the intravenous dextrose.

In twenty-two cases the blood urea was determined before and after the course of treatment. In only one instance was there any evidence of nitrogen retention. The blood bilirubin (icterus index) similarly was normal throughout the course of observation.

COMMENT

Our main object in this presentation is a consideration of the intravenous drip as a method of introducing massive doses of chemotherapeutic agents. We believe that we have demonstrated the possibility of administering truly colossal doses of an effective chemical agent without seriously or permanently damaging the cells of the host. The untoward symptoms that we have noted are not sufficient to deter us from further studies along these lines. It would be a great blunder, however, to employ this method under other than ideal conditions, for serious harm and even death might follow an uncontrolled popularization of our method. It is clearly to be understood that this is a report of an experiment, and that we regard the method as still in the experimental stage and by no means ripe as yet for clinical trial except under ideal institutional conditions.

Aside from the obvious economic advantages to the patient and to the community of an abbreviated and more concentrated therapeutic procedure, the work has a wider public health significance. In the recent article by the members of the Cooperative Clinical Group⁸ under the auspices of the United States Public Health Service and sponsored by the League of Nations Health Organization, it was stated that "the aim in early syphilis may be crisply defined as, first, the prevention of transmission by treatment and, secondly, the individual cure."

Viewed from the point of view of public health, the method has the advantage of requiring institutionalization of the patient during the florid and infective stage of the disease. Under the present ambulatory form of treatment the patient is sent back to mingle with the community during the height of his infectivity, a practice not followed in any other infectious disease. Such a type of management, from the point of view of the community, would be analogous to administering diphtheria antitoxin to a stricken child in an outpatient department and then permitting that child to mingle with the community while the throat cultures were still positive and while the disease was still in its infective stage.

The five days of hospitalization necessitated by the massive dose therapy should afford a maximum amount of protection to the community by the strict isolation of the patient during the greatest period of infectivity. The concentration of therapy within five days will probably reduce the period of infectivity very markedly.

The Cooperative Clinical Group stresses that none of its patients were treated with arsenic alone. Our omission of mercury and bismuth compounds in the treatment of this small group was intentional and was done solely with the idea of executing an uncomplicated experiment. In our future work we plan to give our patients the benefit of combined therapy, and it is fair to assume that even more striking results should be obtained.

SUMMARY

Conscious of the fact that our experiences are extremely limited, we do not wish to stress the comparative figures other than to state that the method suggests a means of control of early syphilis from the point of view of public health and from that of the individual patient, which would warrant further and more extensive clinical trial. Quite aside from the discussion of the treatment of syphilis, it is our belief that these experiments open a new and wide field in

THE EFFECTS OF HYPERPYREXIA PRODUCED BY RADIANT HEAT IN EARLY SYPHILIS

WITH A DESCRIPTION OF A SIMPLE METHOD OF PRODUCING HYPERPYREXIA

NORMAN N EPSTEIN, M D

AND

MAURICE COHEN, M D

SAN FRANCISCO

The application of heat in various ways for the production of an artificial fever has been employed since very early times, and by many races, for the treatment of human disease However, it has only been during the past fifteen years that hyperpyrexia as a therapeutic measure has been critically studied Its use in the treatment of syphilis of the central nervous system has become an established practice, and in many instances strikingly beneficial results have been obtained in which chemotherapy alone had failed to arrest the disease Increasing experience has eliminated much of the danger of the procedure, and the introduction of simple methods of elevating body temperature has increased its availability

Since Wagner von Jauregg's¹ original report in 1918 on the use of malaria in the treatment of dementia paralytica, a number of other methods of inducing hyperpyrexia have been introduced Among these are inoculation with the parasites of relapsing fever and rat-bite fever, the injection of foreign proteins such as a mixed typhoid-paratyphoid vaccine, the intramuscular injection of sulphur in oil, and certain physical methods such as hot baths, heat cabinets, the electric blanket, diathermy and radiothermy The therapeutic results obtained with many of these methods have been similar Since the effect common to all these is the elevation of body temperature, and because the beneficial results are often dependent on the degree of fever obtained, it is generally felt that the hyperpyrexia is the important factor in the treatment rather than the manner in which it is produced

The present report is concerned with the effects of general hyperpyrexia in early syphilis, with particular reference to the dark field examinations, the clinical course of early syphilitic lesions, and the changes in the serologic reactions The problem was undertaken because of the brilliant results obtained by fever therapy in late syphilis involving the central nervous sys-

tem and because of the known susceptibility of *Spirochaeta pallida* to high temperatures It was thought that, if the temperature of all the tissues of the human body could be elevated to the thermal death point of the spirochetes for a sufficient length of time, a complete sterilization of these organisms could be accomplished

During the course of this work a simplified method of producing artificial fever was developed The technic of this procedure will also be reported here

REVIEW OF THE LITERATURE

Animal and In Vitro Experimentation—Weichbrodt and Jahnel² in 1919 showed that serosal syphilitic chancres in rabbits healed more rapidly than usually if the animals were placed at frequent intervals in an incubator heated to 41 C for half-hour periods

Schamberg and Rule³ in 1926 reported that rabbits could be prevented from developing syphilis by a series of eleven hot baths on consecutive days in which the animals' temperature was raised 2.22 degrees C (4 F), provided the baths were given within four days after intratesticular injection of *Spirochaeta pallida* In 1927 they were able to cure two rabbits with primary testicular sores by a series of hot baths in which the animals' temperatures were maintained at from 40.7 C (105.2 F) to 42.8 C (108.9 F) for from fifteen to twenty minutes They were also able to cause the healing of a secondary syphilitic lesion on the foot of a rabbit by fifteen hot baths In 1928 these authors⁴ showed that *Spirochaeta pallida*, heated in vitro at 41 C (105.8 F) for one hour, was no longer capable of producing syphilis in rabbits

Frazier,⁵ experimenting with rabbits and using hot baths, noted a definite inhibition of the clinical progress of a syphilitic infection when the animals' temperatures were elevated to from 41.2 C (106.2 F) to 42.8 C (110.6 F), but no effect when the temperatures were kept between 39.7 C (103.5 F) and 41.1 C (106 F) for twenty minutes

Laps⁶ found that temperatures of 40.2 C (104.3 F) for eighty-five minutes, or 40 C (104 F) for ninety-five minutes were optimum for preventing syphilitic infections in rabbits

Carpenter, Boak and Warren⁷ were able to render syphilitic lesions in rabbits sterile of *Spirochaeta pallida* by multiple unsustained fevers of from 41 C (105.8 F) to 42 C (107.6 F), produced by radiothermy They also found that one febrile period of six hours at from 41.5 C (106.7 F) to 42 C (107.6 F) also destroyed the spirochetes In vitro, they demonstrated that the thermal death-point of *Spirochaeta pallida* was 42 C (107.6 F) sustained for one hour, 41 C

(105.8 F) for two hours, 40 C (104 F) for three hours, and 39 C (102.2 F) for five hours

Kolmer and Rule⁸ showed that, if rabbits were inoculated intratesticularly with *Spirochaeta pallida* four days prior to complete immersion in water at 45 C (113 F) for twenty minutes daily for fifteen days the testicular infection was prevented and the inguinal lymphatic glands became sterile. If the same procedure was followed, with the exception that the testicles were kept out of the water, active testicular lesions developed. This indicates that the effect of the elevation of the temperature was mainly local in these experiments.

It is clear from the animal experimentation and the *in vitro* studies reported that *Spirochaeta pallida* can be destroyed at temperatures that may be induced in man with safety. Two factors are of importance: the height of the temperature within the tissues, and the duration of time that this is maintained.

Clinical Studies—The first clinical studies on the effect of hyperpyrexia produced by physical means on syphilis in human beings were done by Schamberg and Tseng⁹ in 1927. They treated fourteen patients, among

Temperature chart with the blanket method

whom were four cases of secondary syphilis, with a series of hot baths. The cutaneous manifestations cleared promptly. No dark field examinations were reported. They state, however, that no definite conclusions could be drawn from this work but suggested that hyperpyrexia as an adjunct to other methods might prove of therapeutic aid.

Between the years 1925 and 1929, Kerl¹⁰ observed 1,600 cases of early syphilis treated with combined arsenic, bismuth and malarial therapy. He concluded that malarial therapy was of little curative value in early syphilis when the infection was of one or two years' duration, but that it was of definite value in the treatment of late secondary syphilis.

Kemp and Stokes¹¹ in 1929 stated that fever therapy alone will cause involution of primary and secondary

manifestations of syphilis but is markedly inferior to arsphenamine or bismuth compounds.

Neymann and Osborne¹² were unsuccessful in treating primary syphilis by means of hyperpyrexia produced by diathermy.

Bessemans and Thiry,¹³ in an exhaustive report in June 1933, studied the effect of local heat produced by means of hot water baths and diathermy on the lesions of primary and secondary syphilis in man. They recorded the tissue temperature at the base of the lesions by means of a thermo-electric needle. The therapeutic response was dependent on the height and the duration of the temperature obtained. It required a tissue temperature of 42 C for one hour, or 40 C for two hours to render the spirochetes present immobile and avirulent. They showed that the primary and secondary lesions so treated involuted promptly, while those which were not heated progressed in the usual manner.

TECHNIC OF INDUCING HYPERPYREXIA

In the series of cases reported here, hyperpyrexia was induced by means of a specially constructed, electrically controlled heat cabinet, in which an infra-red element was the source of heat.¹⁴ The temperature within the cabinet was maintained between 130 and 160 F, and the humidity was increased by a container of water at the bottom of the cabinet. The patient, without any special preparation, was placed in the cabinet with the entire body enclosed except the head. The temperature, as a rule, rose rapidly, reaching 40 C (104 F) within one and one-half hours. During this time the axillary temperature was noted by means of a recording thermometer and the oral temperature was taken at fifteen minute intervals. When the patient was removed to his bed, the oral temperature and the pulse were taken at one-half hour intervals during the treatment, and then hourly until normal.

When the desired degree of temperature was reached, the patient was removed to his bed, wrapped in warm blankets and encased in a bag made of rubber sheeting. During this procedure, the temperature usually fell from 0.3 to 0.5 degree C, but this was quickly recovered. The patient maintained his fever for a period of from six to seven hours by this means and was then removed from the blankets and given a warm alcohol rub. Hyperpyrexia was considered to begin when a temperature of 39 C was reached. Warm lemonade containing 0.6 per cent sodium chloride and sugar to taste was administered throughout the treatment, the patient receiving 3 or 4 liters.

Blanket Method¹⁵—During the past two months we have devised a simple method of inducing hyperpyrexia by wrapping the patient carefully in blankets and rubber sheeting. Oral temperatures of from 40 C (104 F) to 41 C (105.8 F) could be produced and maintained for six hours by this means. This was accomplished in each of the seventy-five instances in which it was attempted. The accompanying chart illustrates the changes in oral temperature, pulse rate and respi-

15 Technical aid in developing the blanket method of producing artificial fever was rendered by Miss Sarah Nieder.

rations that occur during the average treatment in which the blanket method is used. After the patient is wrapped in the blankets and rubber sheeting there is an even and gradual rise in the oral temperature, usually 0.2 degree C in fifteen minutes or 0.8 to 1 degree C per hour, 39 C (102.2 F) is reached in from three

the principle of preventing radiation of heat from the body surface, which is also an integral part of the technique described by Neymann and Osborne in their diathermy method. These authors¹² also attempted to use blankets alone but were unsuccessful in obtaining temperatures of therapeutic height. They state that

TABLE 1—Clinical Material

Case	Sex	Age	Date of Entry	Stage of Syphilis	Duration of Infection	Location of Lesions	Type of Lesion	Previous Treatment	Period of Observation	Number of Treatments
1	♀	41	9/6/33	Secondary	Lesions present 2 weeks	Face, chest, arms and tongue	Mucous patch under tongue papules on body	None	5 wks	2

33	♀	14		Primary	1 month	Labia	Chancre	None	5 days	2

to four hours and 40 C (104 F) in from four to five hours. The oral temperature is maintained between 40 C (104 F) and 40.5 C (104.9 F) or higher for the period desired. The pulse rarely exceeds 140 per minute and the respiration rate 28 per minute at any time during the treatment. The rate of rise of temperature can be greatly increased by placing a common electric bake over the bed for one to two hours before the heavy woolen blankets, canvas and rubber sheeting are wrapped around the patient. This method employs

they observed a rise of temperature up to 102.2 F in eight hours by this means.

Haddon and Wilson¹⁶ state that they were able to induce hyperpyrexia by means of blankets and hot water bottles, but they do not describe the method or the degree of fever they obtained.

Technic. The patient requires no preparation and may have his breakfast. Long woolen socks are placed

16 Haddon S. B. and Wilson George. *Thermic Treatment of Neurosyphilis*. Pennsylvania M. J. 36: 829 (Aug.) 1933.

on the feet and legs. A heavy woolen blanket, a large canvas sheet and a rubber sheet large enough to cover the entire patient are placed on the bed. Each limb, the trunk and the shoulders are wrapped individually with warm, thin bath blankets. Then the entire body is wrapped in a bath blanket no part of the patient being left uncovered except the face. Seven bath blankets are used.

the temple are taken at one-half hour intervals during the treatment and then hourly until normal.

General Care of Patient During Hyperpyrexia—The care of the patient during the treatment is the same whether the blanket method or the heat cabinet is used. A hypodermic injection of morphine sulphate one-fourth grain (0.016 Gm.) and atropine sulphate 1/150 grain (0.0004 Gm.) is given for restlessness, usually

TABLE 2—*Darl Field Examinations for Spirochaeta Pallida*

Case	Location of Lesion Examined	Before Treatment	After First Treatment			Subsequent
			Immediately	12 Hours	24 Hours	
1	Under tongue	Positive	None seen	No serum obtainable	Lesion not visible	
2	About anus	20-25 per field	5-6 per field with loss of motility	6-7 per field nonmotile	49 hours 15-20 per field mainly nonmotile with occasional actively motile	After 2d treatment 12 motile after 3d treatment, 1 in 2 fields after 4th became negative and remained negative. Biopsy of condylomas after 6th treatment negative.
3	Penis	Negative (6 exams) 4 on recurrent lesion	1 spirochete in 3-4 fields	2 spirochetes in entire preparation		Spirochetes were not found after the 4th day after treating the recurrence.
4	Labia minora	Numerous	8 hrs numerous nonmotile		Negative	Remained negative.
5	Papule on back	Positive	Negative			2 days later positive. 5 days later 2 treatments positive. 7 days later 2 treatments became negative. Inguinal gland negative for spirochetes.
6	Labial ulcer	2 per field	Nonmotile spirochetes	2 slightly motile	Negative	7 days after 1st treatment 2 spirochetes negative and remained negative after 2d treatment.
7	Tongue	Positive	Negative	Negative	Negative	
8	Skin papule	1 in 5-6 fields	Negative	Negative	Negative	Inguinal lymph gland removed 2/3/34 negative.
9	Condyloma	Positive	1 active numerous nonmotile	21 hours negative	26 hours 1 after 1st treatment	3 days after 1st treatment negative.
10	Anus	Positive	Negative	Negative	Negative	Negative. Left inguinal gland removed 11/14/33 negative.
11	Penis	10/27/33 positive	Negative			
12	Vulva	4-6 per field	8-10 motile			7 days after 1st treatment 23 per field. 9 days after 1 in 2 fields. 12 days later no serum. Inguinal gland removed 1/6/34 negative.
13	Penis	Positive	2 per field		Negative	
14	Tongue and vulva	Positive	Positive	Positive	Positive	3d day negative.
15	Penis	Positive	Positive	Negative	Negative	Negative.
16	Mouth penis	Lip positive. Penis positive	Positive	Positive	Positive	Negative on 5th day. Remained positive throughout observation.
17	Vulva	Positive	3 sluggish motile spirochetes per field	Negative	Negative	
18	Penis	Positive		2 spirochetes		2 days after treatment negative. Remained negative.
19	Penis	Positive	3 spirochetes per field	Negative	Negative	Negative.
20	Penis	Positive		1 motile		Negative 3 days later.
21	Labia	3 motile spirochetes		36 hours negative		Negative.
22	Condyloma	Positive	8-10 motile spirochetes per field			Negative after 2d treatment.
23		Positive	Positive			2 days after treatment 1 to 45 fields. After 4d treatment negative.
24	Penis	Positive		12 spirochetes per field		2 days after treatment 15 per field. After 2d negative on 3d examination.
25	Penis	Positive	Negative	Negative	Negative	
26	Penis	Positive	Negative	Negative	Negative	
27	Penis	Positive	12 spirochetes per field	Negative	Negative	
28	Penis	Positive	Negative	Negative	Negative	
29	Penis	Positive	1 spirochete	Negative	Negative	
30	Penis	Positive	3 nonmotile spirochetes	Negative	Negative	
31	Penis	Positive	3 per field active			Negative after 2d treatment.
32	Penis	Positive	Negative	Negative	Negative	
33	Labia	Positive	Positive	Positive	Positive	

The heavy woolen blanket, the canvas sheet and the rubber sheeting are then successively brought over the patient. Two more heavy woolen blankets are used. One covers the lower half of the body, including the feet, the other is wrapped around the entire patient. One hundred and sixty cubic centimeters of hot (100 F) lemonade containing 0.6 per cent of sodium chloride and sugar to taste is given orally at one-half hour intervals, the patient receiving from 3 to 4 liters of the fluid. The oral temperature and the pulse at

when the temperature reaches 39 C (102.2 F), following which the patient may sleep through the treatment. Morphine sulphate one-sixth grain (0.01 Gm.) may be given later if necessary. The patient is carefully observed throughout the period of hyperpyrexia for any unusual reactions. A rapid rise of temperature above 40.5 C (104.9 F) should be controlled by loosening the blankets, fanning the body, administering cool drinks or, if the condition is alarming, by a cool colonic flush. A rapid rise of the pulse rate above 150, a

tendency to collapse, or the onset of tetany are indications for reducing the temperature or discontinuing the treatment. The blood pressure should be taken before the treatment is started and, in the event of an unusual reaction during the treatment, should be retaken. There is a tendency for the systolic blood pressure to fall from 20 to 30 mm of mercury. A decline of the systolic blood pressure below 80 mm of mercury should be considered sufficient to discontinue the treatment. The blood pressure is an excellent indicator of the patient's condition. The necessity of careful nursing

Patients of advanced age, those with serious cardiac or pulmonary disease, or those with a severe degree of arteriosclerosis were not accepted for the treatment. It may be stated that a patient who is not a good physical risk for a major abdominal operation would be a poor risk for hyperpyrexia as well. The development of an infection of the upper respiratory tract during the course of treatments was considered sufficient cause to discontinue them until the patient had recovered. The patient is subjected to a physical examination before each treatment.

TABLE 3—Serologic Changes and Clinical Course of Lesions

Case	Before Treatment			After Treatment			Clinical Course of Lesions

attention during the treatment cannot be over-emphasized. The hyperpyrexia is usually well tolerated, and we encountered no serious untoward reactions in this series. As a rule, the patient recovers from his treatment quickly and is able to return to his work within twenty-four hours. The procedure requires twenty-four hours of hospitalization. Herpes simplex occurred in practically every patient after the first or second treatment but did not recur during the rest of the series. No burns were encountered. In no instance was it necessary to discontinue the treatment because of untoward reactions.

ADVANTAGES OBTAINED FROM USE OF THE
BLANKET METHOD

The blanket method, as described, has been used in a sufficient number of cases to indicate that hyperpyrexia may be regularly induced by this means. It has the following advantages. First, the necessity of expensive electrical equipment is eliminated. Second, there is no danger of electrical burns. Third, in our experience it is less exhausting to the patient than diathermy or the heat cabinet. The rise in temperature is gradual and there is little disturbance of the pulse and respiratory rates.

Fourth, through these advantages it increases the availability of artificial fever therapy

CLINICAL STUDIES

Plan of Clinical Investigation—As our purpose in this problem was to study the effects of hyperpyrexia on the lesions of early syphilis, only patients in the primary and secondary stages of the disease were accepted. All these patients presented lesions in which *Spirochaeta pallida* was demonstrated by dark field examination. Only one patient had received any antisyphilitic chemotherapy, and she had late secondary manifestations from which numerous spirochetes were demonstrated.

There were thirty-three patients in this series (table 1), twelve being females and twenty-one males. The ages varied from 14 to 46, the majority falling between 20 and 30 years. Twelve were in the primary stage and twenty-one presented various lesions of secondary syphilis.

The cases may be divided into two groups: those that were under our complete control for a period varying from two weeks to six months, and those we were permitted to study for five days only before administration of arsphenamine. There were fifteen patients in the latter group and eighteen in the former. With the five-day cases, observations were made on the dark field examinations only, while in the others the course of the clinical lesions and the serologic changes, in addition, were studied. All patients were hospitalized during their period of contagiousness.

Following admission to the hospital, the patient was carefully examined as to his physical fitness for pyretotherapy, and the dark field examinations were recorded. Dark field examinations were done immediately after the period of hyperpyrexia, twelve hours later, and at twenty-four hour intervals until the experiment was concluded. The blood Wassermann and Kahn tests were done frequently, and the effect on the clinical course of the lesions was noted. Several spinal fluid examinations were done. Treatments were given at intervals of from three to four days.

DARK FIELD EXAMINATIONS

Of the thirty-three patients studied, dark field examination immediately after the first treatment failed to show the presence of *Spirochaeta pallida* in ten cases. Dark field examinations were considered negative only when a fifteen minute search failed to reveal *Spirochaeta pallida*. In nine cases the dark field was positive immediately after the first treatment but became negative before the second treatment was given. In several instances a distinct change in the motility of the organisms was noted immediately after treatment. A complete loss of motility in some, or the occurrence of sluggish and occasionally convulsive movements in others, was observed. It is interesting to note that Bessemans and Thiry¹⁵ reported similar observations in their work on the local heating of syphilitic lesions. These changes are evidence of injury to *Spirochaeta pallida*, as shown by investigators¹⁷ using chemical spirocheticides.

Summarizing the results by dark field examination, twenty-two of the cases, or 66⅔ per cent, became negative after the first hyperpyrexia treatment, seven or

21.2 per cent became negative after the second, one, or 3 per cent, became negative after the third treatment, and one case, or 3 per cent, after the fourth treatment. In one patient, a five-day case, the dark field remained positive after two treatments, and in a second patient, except for a fissured papule at each commissure of the mouth, all lesions, including a generalized maculopapular eruption, moist papules over the genitalia, and mucous patches in the mouth, cleared and became negative for *Spirochaeta pallida* after two treatments. The fissures at each corner of the mouth persisted and were still positive for *Spirochaeta pallida* by dark field examination after six treatments, at which time the observation period was concluded.

Table 2 shows the results of the dark field examinations.

CLINICAL COURSE OF LESIONS

In general, it may be stated that the clinical course of the lesions paralleled the dark field examinations. When the spirochetes disappeared, healing took place promptly. The response of the lesions, as well as the dark field examination, was dependent on the character of the treatment given and the location and type of lesion present. When the patient received six or seven hours of a temperature over 40 C (104 F) the result was prompt, with disappearance of *Spirochaeta pallida* from the lesions and rapid healing. When the hyperpyrexia was not so satisfactory and the temperature remained for the most part between 39 C and 40 C, the response was not as satisfactory.

The type of lesions also affected the clinical course, as mucous patches and superficial moist papules healed rapidly after treatment, that is, within from five to seven days, while deeply infiltrated papules and large condylomas involuted more slowly, requiring from two to three weeks. We found that the lesions on the face—that is, the exposed surface of the body—during the treatment involuted more slowly than those on the covered parts of the body. This is illustrated by case 5, in which there was a generalized maculopapular eruption with moist papules over the vulva, mucous patches in the mouth and infiltrated papules over the forehead. All the lesions cleared rapidly except those on the face, where they even increased in size. In case 16 we were unable to cause the fissured papules at each corner of the mouth to heal or become negative for *Spirochaeta pallida* by dark field examination after six treatments, while the rest of the lesions cleared promptly with two treatments.

In three cases of secondary syphilis clinical recurrences were observed. In one, a mucous patch developed on the glans penis eleven days after the eighth treatment. This lesion was positive for *Spirochaeta pallida* but cleared promptly within three days when pyretotherapy was resumed, also becoming negative for *Spirochaeta pallida*. In the second of these cases a mucous patch appeared on the vulva twenty days after the eighth hyperpyrexia treatment. This was positive for *Spirochaeta pallida* and cleared within twelve days after pyretotherapy was resumed. In the third patient a mucous patch developed, positive by dark field for *Spirochaeta pallida*, on the lower lip ten days after the eighth hyperpyrexia treatment. In none of the patients with primary syphilis were recurrences observed.

SEROLOGIC CHANGES

Of the eighteen cases under observation a sufficient length of time for serologic changes to be noted, fifteen

17 Wilkes Weiss, Dorothy, and Weiss, Charles. Experiments on the Purification of Cultures of *Spirochaeta Pallida* by Chemical Method. *J. Infect. Dis.* 38: 289 (April) 1926.

presented strongly positive blood Wassermann and Kahn reactions, and three were negative before treatment. The latter remained negative during their periods of observation, that is, two, three and six weeks, respectively. In those with strongly positive serologic reactions, there were some temporary fluctuations, but all showed strongly positive blood Wassermann and Kahn reactions at the conclusion of their hyperpyrexia treatments.

Spinal fluid examinations were done in seven patients before treatment, in four of these the spinal fluid was reexamined after treatment. In three cases the spinal fluid was examined only after treatment had been given. A total of fourteen spinal fluid examinations was done, but none showed definitely abnormal changes.

Table 3 presents the serologic changes.

EFFECT ON THE PATIENTS

Among those patients with secondary syphilis, all experienced symptomatic relief. Patient 5 was of interest, as at the time of entry she had a fever as high as 38.5 C (101.3 F) for several days. Immediately following the first treatment her temperature became normal and remained so.

COMMENT

From the observations reported here concerning the effects of hyperpyrexia on the lesions and clinical course of early syphilis, it is evident that artificially produced fevers of from 39 C (102.2 F) to 40.5 C (104.9 F) and maintained for a period of six or seven hours do not sterilize the human body of *Spirochaeta pallida*. This is shown by the three clinical recurrences that developed after the hyperpyrexia treatments had been discontinued. The fact that the patients who had strongly positive blood Wassermann and Kahn tests on entry showed no permanent change after hyperpyrexia would indicate that the infection had not been greatly affected.

Experimental workers have shown that *Spirochaeta pallida* will die at 40 C (104 F) in two hours in vitro, and also in human tissues, and in shorter periods of time at higher temperatures. In the hyperpyrexia treatments as given in this work the optimum temperature of 40 C (104 F) is not obtained in all the tissues of the body. The temperature of the skin of the uncovered portion of the body, that is, the face, is lower than that of the covered parts of the body at the height of the treatment, and probably never exceeds 39 C (102.2 F). It is of interest that lesions which were on the face of patients regressed much more slowly than those on the covered parts of the body. According to the work of our colleague Dr. John J. Sampson, there is a wide variation in the temperature attained by the skin, the subcutaneous tissue, the muscles and the venous blood as measured by means of a needle thermocouple. He found that the temperature of the venous blood in the median basilic vein rose more slowly than the other tissues and did not exceed 39.4 C (102.9 F), even when the oral temperature was 40.7 C (105.3 F). In general, the venous blood remained from 1 to 3 degrees C below the oral temperature. The temperature of the subcutaneous tissue also remained considerably below the oral temperature. The temperature of the intramuscular tissue exceeded the oral temperature by from 0.8 to 1.4 degrees C, and the rectal temperature tended to approach these ranges.

Neymann and Osborne¹² also noted that the temperature of the subcutaneous tissue rose more slowly than the other tissues of the body. As they state, it is probably because of the inability to raise the temperature of the entire body to a sufficient height that accounts for the unsatisfactory results obtained by others and ourselves in the treatment of early syphilis by means of artificial fever.

The prompt disappearance of *Spirochaeta pallida* from lesions exposed to a high temperature substantiates the view that this organism can be destroyed by temperatures between 40 C (104 F) and 41 C (105.9 F). If a method could be devised that would raise the temperature of all the tissues of the body to a proper height, the eradication of early syphilis by this means might be accomplished.

A description of a method of inducing hyperpyrexia by the use of blankets alone is included in this report. Its simplicity and the fact that expensive equipment is not needed should increase the availability of this mode of therapy. The treatment given in this way has been less exhausting to the patient than other methods that we have used.

SUMMARY AND CONCLUSIONS

1 In thirty-one of thirty-three cases of early syphilis, or 94 per cent, the dark field examination was rendered negative for *Spirochaeta pallida* by means of hyperpyrexia alone.

2 The clinical lesions of early syphilis healed promptly in all cases in which the dark field examination became negative.

3 Three clinical recurrences were observed after cessation of the treatment.

4 The serologic reactions were not reversed from positive to negative in any case.

5 Inability to elevate the temperature of all the tissues of the body to the thermal death point of *Spirochaeta pallida* probably accounts for the failure to sterilize the body of these organisms.

6 Hyperpyrexia alone is not a satisfactory method of treatment of early syphilis.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs CHARGIN, LEIFER AND HYMAN
AND DRs EPSTEIN AND COHEN

DR. HOWARD J. PARKHURST, Toledo, Ohio. Drs. Epstein and Cohen have produced therapeutic fever in a series of cases by a method that is interesting because of its simplicity, availability and cheapness. I refer to the blanket method, which may be carried on very well in the home, the only requirement being the constant supervision of a thoroughly experienced nurse. Like all other methods in use, it has shortcomings. It is unfortunate that the temperature of all parts of the human body cannot be raised uniformly to the thermal death point of the spirochete. Perhaps in the future this may be accomplished by some combination of radiant and penetrating heat, or otherwise. Much more work is required. An important point that was not brought up in this paper is the possible value of fever therapy not used alone but as a supplement to the usual chemotherapy in the treatment of early syphilis. Richet and his co-workers in France and Tenney in New York have published favorable reports, and further investigations should be made.

DR. CLYDE L. CUMMER, Cleveland. If found free from untoward results and undue complications, the method proposed by Dr. Chargin and his co-workers would present great advantages. However, the number of cases is insufficient for final conclusions as to the clinical and serologic results or the frequency and seriousness of the complications, and the time period

covered by the observations is not long enough to judge of the efficiency of cure as compared with the generally accepted methods which have been so carefully studied by many workers since Ehrlich's discovery. Certain questions arise. First, what will be the effect of condensing treatment on the development of natural resistance, and when the rest periods come, what about the incidence of neurorecidives? What about the later effects on liver, skin and cardiovascular system and the nervous system? The well recognized tendency of arsenic to accumulate and the occurrence of remote effects sometimes after the lapse of years makes one wonder what one could expect with this method of massive treatment. The percentage of neuritic symptoms was high. While they cleared up in some cases after the lapse of some time, will there be permanent damage? The number of complications impressed me as being rather high, compared with the figures of the combined research of Cole, Moore, Weil, Stokes and O'Leary, in which the total reactions range between 1920 to 1931 in some 163,000 injections as about fifteen in a thousand, or 15 per cent. The figures of Drs Chargin, Leifer and Hyman showed that the skin reactions were present in 33 per cent of cases, polyneuritis in 32 per cent, and fever in 80 per cent or more. Doubtless some patients showed more than one of these sequelae. The basis of comparison is not fair, because these figures are based on patients and these group studies were based on the number of injections. The chief drawbacks to the method are the effects on the veins, the possibility of later systemic effects, the high incidence of immediate skin and nerve complications, and the uncertainty of permanently curative results as compared with the well established routine, and the requirement of hospitalization, which prohibits general employment in large clinics and in many private patients.

DR. WALTER M. SIMPSON, Dayton Ohio. I will restrict my discussion to the paper by Drs Epstein and Colien. It is now apparent that simple fever production is the common denominator of all the methods that have been employed for the fever therapy of syphilis, whether malaria, relapsing fever, rat-bite fever, foreign protein substances, hot baths, electric blankets, diathermy, radiotherapy or the newer radiant heat methods. There is no evidence that the malarial plasmodium possesses intrinsic merits. I have completed the treatment of some fifty cases of neurosyphilis, and the results obtained with a variety of physical modalities including diathermy, radiotherapy and radiant heat methods, indicate that they are at least comparable to those obtained with malaria. In all these cases I have combined antisyphilitic chemotherapy with artificial fever. Many reports in the literature indicate that the combination of fever therapy and chemotherapy gives the most prompt and lasting results. The application of fever therapy to early syphilis is still strictly experimental. In forty-six patients with fresh syphilis in whom positive dark fields were obtained and in whom the fever was rapidly elevated to 106 F and maintained there for five hours, I have never succeeded in finding spirochetes in the primary lesion after the first treatment with fever. I have made thermometric gradient studies which indicate that there is no essential difference in the deep temperature levels produced by either radiant heat or high frequency methods. The two are equally effective. One important drawback to some of the physical methods is the slow induction of fever. Any method that prolongs for from two to four hours the elevation of temperature to 106 F provides an exhausting experience for the patient. This is readily overcome by utilizing one of the methods available for the rapid induction of fever, which can then be controlled readily for maintenance at the desired temperature level. All my patients are now being treated as ambulatory patients. I have finished the treatment of some 325 patients without accident. No patient has been injured by the treatment, and a minimum course of fever therapy for syphilitic patients has been fifty hours of sustained fever, usually given in ten weekly treatments of five hours each, with the fever sustained between 105 and 106 F. In the present state of knowledge it is hazardous to carry out this treatment in any place but an institution, under the careful and constant supervision by a physician who has made himself thoroughly aware of all the medical and physical principles involved utilizing trained nurse-technicians.

DR. HAROLD N. COLE, Cleveland. It may be that it would be better to have a method that will bring the temperature up to 106 rapidly and hold it at a level and then drop it, but it will not be possible for different institutions to have expensive machines such as Dr. Simpson has or the one that has been installed over at the City Hospital. But I think this should be followed out, and it may work very well along with the other methods in the treatment of syphilis. I am interested in the drip method that Dr. Chargin and his co-workers have suggested. It is true that there seemed to be quite an increase in the amount of toxic symptoms from this method and that it will have to be toned down, but the idea that these authors have started on is very good. If it should be possible to use somewhat smaller doses and immediately follow them up with bismuth therapy not giving a lapse of treatment this might be a valuable addition to the treatment of syphilis.

DR. HARRY M. ROBINSON, Baltimore. In discussing the paper by Drs Chargin, Leifer and Hyman, I apologize for attempting to talk on a technic with which I am not familiar. There is some gap between animals and human beings that it has never been possible to fathom. One can accomplish in animals easily what one apparently can never accomplish in human beings. The danger of mass therapy always brings forth to me the danger of abortive therapy. Some patients will become negative serologically with one or two injections of arsphenamine of moderate dosage, 0.3 Gm for a female, 0.4 Gm for a male, and a comparable dose of neoarsphenamine. Other patients, as Dr. Chargin and his co-workers have shown will not become seronegative under two courses of arsphenamine interspersed with bismuth compounds. Certainly the future danger of neurorecurrences or cardiovascular disease is very great, and one must tread this matter of therapy gingerly. In the University Hospital clinic of which I have charge, treatment for two Negro patients of 0.45 Gm. each had been ordered. I advised that my associate use a 0.9 Gm ampule, dividing it giving half to one patient and half to the other. When we went to look for the 0.9 Gm ampule it was nowhere to be seen. Instead, there were two 4.5 Gm ampules lying on the table, and each of these Negro patients had received at one injection 4.5 Gm. Strange to relate, one patient developed no untoward reactions, and the other no more than moderate nausea and vomiting. It is also strange in view of the experience of Dr. Chargin and his co-workers, that the Wassermann reaction did not become more rapidly negative and in one patient we had to continue the treatment as any other patient received it. The other patient failed to return and we could never locate him.

DR. NORMAN N. EPSTEIN, San Francisco. There are three points I want to emphasize. First, although radiant heat is a simple method of producing hyperpyrexia, this procedure should be done with extreme care. As Dr. Simpson has stated, it requires a trained nurse in constant attendance and physicians experienced in fever therapy. Second, several patients can be treated simultaneously. One nurse can take care of four or five patients if placed conveniently close to one another. The temperature can be raised rapidly by radiant heat, combining the blanket method with a simple electric baker over the bed for one or two hours. Third, the patient is ambulatory and remains in the hospital for only twenty-four hours for a single treatment. In this way fever therapy can be made a part of routine antisyphilitic therapy without interfering with the economic status of the patient. Any patient with central nervous system syphilis who fails to react satisfactorily to a reasonable amount of chemotherapy should be given fever therapy as well.

DR. LOUIS CHARGIN, New York. I realize that our experience with this method of therapy has been too limited to warrant its recommendation as a routine method. Our experience, however, does demonstrate that it merits further trial, particularly in the treatment of early syphilis. Such a trial should, however, be given under fully controlled conditions, which include proper choice of material, hospitalization of the patients, accuracy in technic and careful observation during and after treatment. I should like to repeat that this method of therapy is an approach to Ehrlich's *therapia sterilisans magna*. From knowledge gained in experimental animal syphilis and experience in human syphilis it is fair to assume that if a scheme can be devised that will permit of the massing of the organic

arsenicals in sufficient quantity with safety, such a method will offer the best outlook for a cure of syphilis in the greatest percentage of cases. The intravenous drip method is an effort in this direction. In administering such large amounts of the arsphenamines in so short a space of time, we naturally feared the toxic effects of the arsenic, but we are glad to be able to state that these have been comparatively mild in character. Our greatest difficulty has been with polyneuritis. The percentage of cases observed has been higher than is usual with the other intensive method of therapy, but all the cases have cleared up in a comparatively short time. We hope to continue this work, but expect to use arsphenamine instead of neoarsphenamine, since the former is more stable. Perhaps we shall thus avoid the high percentage of polyneuritis. Dr. Cummer has brought up the question of natural resistance. It seems that the majority of opinion is not in favor of waiting for immunity to develop. The tendency seems to be rather to treat intensively as soon as the diagnosis has been established. Dr. Cole's suggestions are well taken. In the next series of cases we hope to make use of both bismuth compounds and arsphenamine and can perhaps show even better results than in this series of cases. The experience of Dr. Robinson is by no means unique since there are already reported in literature several such instances, in none of which there seems to have been serious damages as a result of these enormous doses of arsenic.

PULMONARY MANIFESTATIONS IN HUMAN TULAREMIA

A CLINICAL STUDY BASED ON THIRTY-FIVE UNSELECTED CASES

STAIGE D. BLACKFORD, M.D.
UNIVERSITY VA

The pleuropulmonary manifestations of tularemia have never been the subject of a detailed clinical report, although they are now regarded as a part of the disease.¹ This report is based on an analysis of the clinical evidence of pleuropulmonary involvement discovered in thirty-five cases in which the diagnosis of tularemia was made either by an agglutination test or by the recovery of the organism.

Data relative to the individual tularemic infections are listed in table 1. The respiratory symptoms, physical signs and roentgenologic diagnoses of the thirty-five cases are presented in table 2. Both clinical and roentgenologic evidences of intrathoracic disease were found in seventeen patients and roentgenologic evidence alone was present in fifteen. Chest films in thirty-two of thirty-four patients were abnormal and roentgenologic changes in these films are the subject of a separate report.² This presentation deals primarily with the seventeen patients in whom clinical indications of pleuropulmonary involvement were found. These cases will be grouped for discussion under three headings:

1. Tularemic pneumonia, seven cases
2. Tularemic bronchitis, seven cases
3. Tularemic pleural effusion, three cases

From the Department of Internal Medicine, University of Virginia Hospital.

TULAREMIC PNEUMONIA

Physical and roentgenologic signs of pulmonary consolidation were detected in seven cases (20 per cent of the entire series). In this group the diagnosis of tularemia was difficult because the usual clinical criteria were often lacking. Tularemia was suspected in one instance (case 34) from the history and from bilateral ulceroglandular lesions that occurred before the pneumonia. It was proved subsequently by the agglutination test. In another (case 10), enlargement of the cervical glands appeared several days after the pneumonia was detected, but the diagnosis of tularemia was not made until a biopsy of these glands two months later suggested the repetition of the agglutination. Ulceroglandular lesions were not apparent in the remaining five patients of this group, and the diagnosis of tularemia was based on agglutination tests made because of fevers of unknown origin (cases 1, 5 and 26) or because of chest conditions of unproved etiology (cases 28 and 30).

The symptoms of pneumonia in this group were variable and in general were less severe than those seen in ordinary pneumonia. All seven patients had some degree of cough, but usually it was not serious. There was no rusty sputum. The sputum was profuse and bloody in one instance (case 5), in which there was also a lung abscess. Chest pain was absent in five, but it was severe in two (cases 1 and 28). Some patients had chills at the time of the onset of tularemic symptoms, but chills were absent at the beginning of the pneumonia. In four patients (10, 26, 28 and 34), bronchitis preceded or was associated with the consolidation. The physical signs were those usually found in pneumonia and in most cases they were lobular in distribution, however, in at least one (case 28), the involvement was both lobular and lobar. In cases in which the time of consolidation could be determined, it was detected on the second, fifth, sixth, eighth, eighth and sixteenth day after the tularemic infection. The physical signs persisted for from a few days to three weeks. The temperature fluctuated from 103 to 106 F., and in those patients who survived, the fever remained after the disappearance of signs. The pulse rate was remarkably slow in relation to the fever, in no case was it consistently faster than 110. Rapid respiration and cyanosis were noted only in the terminal stages of the fatal cases. The leukocyte count was within the limits of normal with the exception of one case (case 10). Three (patients 5, 26 and 34) of these seven patients died.

Detailed reports of case 5^{1a} and of case 30² will be found elsewhere. The other five cases of tularemic pneumonia (cases 1, 10, 26, 28 and 34) are presented here with the primary emphasis on the pulmonary involvement.

CASE 1—A farmer aged 34, admitted, July 25, 1927, complained of nausea, vomiting, backache and prostration of eight days' duration. Routine studies revealed nothing except a temperature of 102.8 F. In view of the season, the fever and the normal leukocyte count, treatment for typhoid was instituted. August 8, pleurisy developed on the left and three days later typical signs of pneumonic consolidation were noted. August 12 a roentgenogram confirmed the diagnosis of pneumonia. The fever began to subside August 16 and was gone by the 20th. The patient was discharged, September 7, with a diagnosis of typhoid in spite of repeated negative Widal tests and of many negative cultures of the blood, urine and stool for typhoid bacilli.

The subsequent recognition of a case of tularemia caused this patient to be recalled for an agglutination test, Feb 7, 1928, which was positive (1 80) Roentgen films in 1928 and 1933 have revealed marked fibrosis in the chest

CASE 10—A feeble-minded boy played with the skin of a freshly killed squirrel, Nov 28 1929 The next day he had four convulsions and was admitted to the hospital that night in a convulsive state, with a temperature of 105 F Dulness and increased whispered voice were noted in the left apex Laboratory studies, which included agglutination tests for typhoid undulant fever and tularemia as well as lumbar puncture, were essentially negative The leukocyte count was 14 000 December 9 a roentgenogram revealed pneumonic infiltration with apparently central softening in the left upper lobe. During his first weeks in the hospital the boy presented a wide variety of symptoms Pus was aspirated from a deep cervical abscess, which developed about December 15

Necropsy—Four hundred cubic centimeters of fluid and, apparently, pneumothorax were found on the left Fibrinous exudate covered the pleura on both sides and there was extensive purulent involvement of the tracheobronchial glands Small pneumonic patches with a few minute zones of necrosis were present in the left upper lobe The left lower lobe was almost completely consolidated, with a central cavity, 3 cm in diameter, connecting with a bronchus The right upper lobe was in an earlier stage of consolidation Several small zones of focal necrosis were noted in the right middle and lower lobes Bacterium tularense was recovered from animals inoculated with macerated lung tissue

CASE 28—A farmer, aged 68 began to have "dizzy spells," July 26, 1933 A sharp pain in the right side of the chest with chills, fever, nausea and vomiting began the following day Because of these symptoms he was admitted July 31 He had no respiratory symptoms other than the chest pain

* The first thirteen cases have already been reported briefly (Blackford & D. Virginia M. Monthly 58:10 [April] 1931) Cases 15, 19, 30 and 35 are being reported by Archer Blackford and W. W. Waddell. Cases 4 and 23 have been reported in detail (Blackford & Virginia M. Monthly 60:107 [May] 1933) Cases 20, 21 and 22 have been reported by W. W. Waddell Jr. and W. C. Willis (J. Pediat. 2:187 [Feb.] 1933)

† T typhoidal UG, ulceroglandular G glandular OG oculoglandular

Jan 15 1930 a cervical gland was removed for diagnosis Discovering no acid-fast organisms, the surgical pathologist suggested a second agglutination test for tularemia This was positive (1 160) on January 30, which was the first day with out fever He was discharged, February 9 He was readmitted in May on account of bilateral conjunctivitis the cause of which could not be determined No recent information about this patient has been obtainable

CASE 26—A farmer aged 24, skinned a rabbit during the afternoon of June 30, 1933 The next morning as he started to work he fainted and later he became feverish with headache, weakness and anorexia He was admitted, July 5, with cough, prostration and a temperature of 105 F Generalized bronchitis was found on physical examination but the routine laboratory studies were negative July 9 signs of consolidation were noted in the left lower lobe A roentgenogram on July 11 showed consolidation from the second to the fifth rib with a central area of rarefaction about 3 by 5 cm on the left and infiltration in the second interspace on the right. Three days later physical signs of extensive bilateral consolidation were present and the agglutination test was positive for tularemia (1 80) The patient died suddenly the next day

Chest examination revealed atypical signs of either fluid or consolidation in the right side of the chest posteriorly The temperature was 103.2 F Two days later, thoracentesis was attempted but no fluid was found August 3, the chest signs were definitely those of pneumonia On the 8th, tularemic agglutination, taken because of the typical character of the chest condition, was positive (1 40) the titer increased to 1 320 in later examinations In roentgenograms of the chest made on the 22d, after the physical signs had disappeared, evidence of pneumonia in the right base was still visible. The patient was discharged, August 27 Chest films in January 1934 showed residual signs of bronchitis

CASE 34—A housewife aged 42 dressed a rabbit, Nov 2, 1933 Three days later she went to bed with chills, fever and headache. She was admitted, November 10, with a temperature of 104 F Multiple bilateral ulcerations on the hands and bilateral epitrochlear and axillary adenopathy were obvious There were a few rales in the right hilus area but no respiratory symptoms The laboratory studies were unimportant Roentgen films on admission revealed great enlargement of the right hilus Definite physical signs of pneumonia were first found on November 15 In the roentgenograms of the 18th,

a further increase in the enlargement of the right hilus with a surrounding pneumonic area was noted and there was a small area of necrosis near the hilus. The patient became increasingly toxic and died, November 19. A blood specimen obtained after death gave the first positive agglutination for tularemia (1:160).

TULAREMIC BRONCHITIS

Clinical bronchitis was diagnosed in twelve cases. In only seven of these twelve was the bronchitis uncomplicated. These seven patients gave typical contact histories and exhibited the ulceroglandular lesions of tularemia.

All these patients had a moderate to severe cough, generally beginning within a week of the tularemic inoculation and continuing for from a few days to more

tration, productive cough, headache and periods of delirium. Scattered patches of fine rales were heard under the left scapula, and a tentative clinical diagnosis of bronchopneumonia was made. Roentgen study on the 30th revealed bronchial changes in this area, but pneumonic infiltration was indefinite. The fever subsided about two weeks after admission. Agglutination tests for tularemia became increasingly positive to a titer of 1:640. The patient was discharged, Jan. 2, 1928. He died of accidental injuries April 28, 1929.

CASE 14—A house painter, aged 51, skinned a rabbit in October 1927. A few days later he noticed an ulcer on the hand and glands in the axilla. He was confined to bed for ninety-three days on account of febrile symptoms and a severe cough. The cough persisted after convalescence and was so severe that the patient had to stop working. Nov. 17, 1929, the patient said that he "coughed up about a cupful of bloody

* x indicates a roentgen finding not apparent in the first films but present in a subsequent film.

than thirty months. In four cases (3, 14, 19 and 23) the cough was unproductive. None of the patients experienced chest pain. The dyspnea recorded in one instance (case 3) was probably of cardiac origin. Rales were heard in every case, they were localized and rather fine in some instances, generalized and coarse in others. In two cases (3 and 19) there were physical signs suggestive of consolidation but the suspicion of pneumonia could not be confirmed by roentgen studies. Patients 3 and 14 had high and protracted fevers, the other five were treated in the outpatient clinic after mild febrile reactions at home.

Acute and chronic bronchitis are illustrated by the reports of the two patients (3 and 14) who were hospitalized

CASE 3—A banker aged 63, skinned a rabbit Nov 16, 1927. The next day he complained of fever, headache and weakness. He was admitted November 27 with a fever of 103.6 F pros-

"sputum" during one twenty-four hour period. Following this similar episodes occurred several times a month and in addition he suffered from dyspnea, chest pain and tiring easily. However, all these symptoms gradually improved until the time of his admission. He entered the hospital, April 15, 1930, because he thought he had tuberculosis. A few scattered small and medium moist rales were heard in the left apex anteriorly, and a questionable clubbing of the fingers was noted. Roentgen study of the chest revealed enlargement of both hilus zones and many discrete areas of calcium deposit, but there was no evidence of active tuberculous infection. Sputum examinations for acid-fast organisms were negative. Tularemic agglutination was positive (1:160). The patient left the hospital against advice two days after admission and no subsequent information has been obtainable.

TULAREMIC PLEURAL EFFUSION

A diagnosis of pleural effusion was made in four cases in this series. Pleural effusion was found once at necropsy in a pneumonic case (case 26), the diag-

nosis in the other three (cases 2, 12 and 35) was made during life and the fluid aspirated and studied. In these three surviving cases the diagnosis of tularemia was obvious once (case 12) from history and ulceroglandular lesions, but tularemia was not apparent in the other two (cases 2 and 35). Patient 2 was thought for two years to have tuberculosis of the pleura and lung. The diagnosis of tularemia was finally made when the patient requested an agglutination test after reading about the disease in the newspapers. The other was believed to have a tuberculous effusion until tularemia was proved by the routine agglutination test for an obscure condition of the chest.

These three patients had cough, which was productive in one instance (case 2). Chest pain was severe in two (cases 2 and 35) and mild in one (case 12). There was marked dyspnea in one (case 35) and slight dyspnea in the other two (cases 2 and 12). Patient 2 had physical signs of bronchitis, pleural fluid and consolidation. Another (patient 12) had probable consolidation in addition to the effusion. The third patient (35) was admitted for the removal of fluid from the left side of the chest and reported that fluid had been aspirated from the right side of the chest three months previously.

High fevers, relatively slow pulse rates and normal leukocyte counts characterized all three cases.

The pleural fluid in each instance was slightly cloudy and straw colored. The specific gravities varied from 1.022 to 1.042, the total protein in the fluid from 4.5 to 5.6 per cent. The highest cell count was 3,400. Lymphocytic cells predominated in all the differential counts. No acid-fast organisms were identified in the stained smears and no evidence of tuberculosis was obtained from guinea-pig inoculations. Efforts to isolate *B. tularensis* from the fluids by animal inoculation and culture, made in two instances (cases 12 and 35), were unsuccessful, the same fluids, however, agglutinated the organism in high dilutions.

Case 35 is reported in detail elsewhere.² The other two are presented here.

CASE 2—A schoolboy, aged 19 years, admitted, Aug. 17, 1927, had a fever of 103.8 F. He had been sick three days with chills, fever and a pain in the right side of the chest. Physical examination and laboratory studies were essentially negative. Owing to the season and a high fever with a normal leukocyte count a tentative diagnosis of typhoid was made in spite of the fact that the patient had recently completed a series of typhoid inoculations. During the first ten days in the hospital a moderate cough with dyspnea developed, and on August 27 numerous diffuse squeaks were heard in both lungs. The following day an extensive pleural and pleuropericardial rub was present over the left side, and it was thought that there were also signs suggestive of consolidation. By the 31st, the rub was replaced by signs of fluid. Aspiration on this date removed 10 cc. of a slightly cloudy straw-colored fluid with a specific gravity of 1.042 and a total protein content of 4.5 per cent. There were 90 per cent small lymphocytes in the differential smear. No acid-fast organisms were found and a guinea-pig was inoculated but subsequently lost. September 1, therapeutic thoracentesis removed 850 cc. of similar fluid. Definite signs of multiple small areas of consolidation were found in both lungs on the 6th. The high fever began to subside about ten days later. No definite evidence of fluid was seen in the first roentgen films, taken on the 29th, but it was thought that there was evidence of tuberculosis in the parenchyma of the lung. The patient was sent to a tuberculosis sanatorium October 25 with a diagnosis of tuberculous pneumonia and tuberculosis of pleura, in spite of the fact that

repeated sputum examinations for acid-fast organisms had been negative. The patient was discharged from the sanatorium in June 1928, after gaining 40 pounds (18 Kg.). He returned to the hospital, Jan. 15, 1930, asking that a blood test for "rabbit sickness" be done because he remembered having skinned a sick rabbit a few days before his first admission to the hospital. The agglutination was positive (1:320). Peribronchial infiltration was seen in roentgen films taken in October 1933.

CASE 12—A housewife, aged 25, skinned a rabbit, April 9, 1930. Two days later there was a sudden onset of fever, accompanied by aching, nausea, vomiting and a hacking cough. She was admitted, April 14, with a fever of 103.2 F. Ulceroglandular lesions were found and a tentative diagnosis of tularemia was made. Chest examination and laboratory studies were negative. Tularemic agglutination on April 28 was positive (1:1,280). A roentgen film of the chest on the 30th indicated probable bronchiectasis in the right base. May 6, local roentgen therapy to the ulcer and glands was instituted with some relief of symptoms. Defervescence began on the 8th, but daily examinations of the chest were continued. Signs of fluid in the right base were definite by the 14th. A roentgen film on this date revealed an increase in the density previously noted, but it was thought that there was insufficient evidence to warrant a diagnosis of pleural effusion. On the 17th a diagnostic thoracentesis removed 400 cc. of slightly cloudy straw-colored fluid with a specific gravity of 1.022 from the right pleural space. This exudate contained 3,400 cells per cubic millimeter, with 72 per cent lymphocytes in the differential count. No acid-fast organisms were found and guinea pig inoculations were negative for both tuberculosis and tularemia. *B. tularensis* was not recovered in the special mediums used, but the fluid agglutinated the organism (1:640). The patient was discharged, May 23. A roentgen film in September 1933 revealed a moderate increase of the lung markings in the right base.

COMMENT

Tularemia has been shown to affect the thoracic viscera in a high percentage of cases which came to necropsy, but this study demonstrates for the first time that pleuropulmonary infections are frequent in patients who recover from the disease. Clinical methods detected lung or pleural involvement in approximately half of this unselected series, and roentgenograms revealed abnormalities in the chest in more than 90 per cent.

Physical and roentgenologic examinations established the presence of consolidation in one fifth of this entire series and of those patients who were first seen within forty days of the onset of tularemia, pneumonia was found in one fourth. These figures may not represent the true frequency of pulmonic consolidations in all tularemic infections, since in rural areas only the most severe cases are hospitalized. On the other hand, these data indicate that pneumonia is a much more common manifestation of tularemia than would be expected from the fact that only three cases³ have been published under the name of "tularemic pneumonia." This study points out further that, while pneumonia is one of the most serious manifestations of tularemia, it is not so fatal as is generally believed. Only two recoveries⁴ after consolidation in tularemia have been reported. Four of these seven patients with proved consolidation survived. There was no definite proof of lung necrosis in any of these surviving patients. Conclusive roentgenologic evidence of "central softening" in the consolidated areas was found in each of the three fatal cases. This "central softening" represented cavitation.

in the two patients who came to necropsy. The pathologic studies in these two instances were entirely consistent with the observations reported in tularemic pneumonia.

Bronchitis alone or in conjunction with other pulmonary disease was found clinically in more than one third of this series, and there was roentgenologic evidence of peribronchial thickening in three fifths of all the patients. The prognosis was not serious when bronchitis alone was present. Patients in whom clinical bronchitis was uncomplicated were usually no more ill than those without clinical indications of respiratory involvement, and none of them died. In the absence of necropsy studies of uncomplicated cases it could not be proved that the bronchial changes resulted from tularemia and not from secondary infection. However, inflammation of the bronchi was found in an unconsolidated portion of the lung in one of the patients dying of tularemic pneumonia, and this finding suggests that the bronchitis was also due to tularemia. The frequency with which bronchitis followed tularemic infection is a further indication that it was a part and not a complication of the disease.

Fluid in the pleural cavity was found in four of these thirty-five cases. In three instances it was associated with physical signs of pneumonia. The exudate was aspirated for diagnostic examination in three of these four patients. These exudates were strikingly similar on routine laboratory study to the exudates found in tuberculous effusion, but two of the fluids agglutinated *B. tularensis*, and tubercle bacilli were demonstrated in none of them. The effusions were presumably due to tularemia, since previous and present necropsy studies have shown that pleural fluid may be associated with pneumonia of definitely tularemic origin.

Gudger¹ has called attention to the fact that pulmonary lesions are prominent in certain cases of the typhoidal type of tularemia and that these pulmonary manifestations are often diagnosed with difficulty. These statements were confirmed in this study. Seven of the eight patients with the typhoidal type of infection had serious pulmonary lesions. The chest symptoms and signs were outstanding in these cases and the diagnoses of tularemia were made only by agglutination tests. When tularemia is not recognized as the cause of the respiratory involvement, diagnoses of tuberculosis or of bronchopneumonia may be made erroneously.

In regions in which tularemia is prevalent, the disease should be considered when suspected pulmonary tuberculosis cannot be proved. Tularemia agglutinations should be obtained also in all atypical pneumonias, particularly if they are accompanied by a high fever with a relatively slow pulse rate and a relatively low leukocyte count. It has been a local custom in the past year to secure tularemic agglutinations in all unusual chest conditions, and three of the present cases were recognized as tularemia only as a result of this routine procedure.

SUMMARY

Thirty-five consecutive cases of tularemia were reviewed with reference to the pleuropulmonary manifestations of the disease during life. Clinical evidences of such involvement were found in seventeen of the thirty-five cases. Pneumonia was proved by physical and roentgenologic examinations in seven instances (20 per cent of the entire series), clinical bronchitis alone,

as evidenced by cough and rales without other signs, was found in seven other patients (20 per cent), and pleural fluid was aspirated from three patients (8.6 per cent).

PULMONARY MANIFESTATIONS IN HUMAN TULAREMIA

A ROENTGENOLOGIC STUDY BASED ON THIRTY-
FOUR UNSELECTED CASES

VINCENT W. ARCHER, M.D.
STAIGE D. BLACKFORD, M.D.
AND
JAMES E. WISSLER, M.D.
UNIVERSITY VA

Thirty-five cases of tularemia have been recognized at the University of Virginia Hospital since 1927. Thirty-four of the diagnoses have been confirmed by characteristic agglutination reactions, the remaining one by recovery of the organism after death.

Roentgen study of the chest had not been made in a single case in this series prior to the tularemic infection. Chest films have been taken in thirty-four of the thirty-five cases at some time subsequent to the inoculation. Roentgenograms of the chest were obtained in eighteen patients during the active stage of the disease (i.e., within three months of inoculation), eight of these returning after recovery for further roentgen examination. Chest films after recovery were made in sixteen of the remaining cases. It is unfortunate that films were not obtained during the active stage of the disease in all the cases, but it was not until late in this series that it was realized that positive pulmonary changes are so uniformly present. In recent cases, early and serial films are made as a routine.

PULMONARY MANIFESTATIONS IN ACTIVE TULAREMIA

The roentgen films in this group have been reviewed and interpreted in accordance with the following classification:

Pulmonary consolidation, seven
Peribronchial thickening, seven
Pleural effusion, three
Nodular infiltration, one

PULMONARY CONSOLIDATION

Tularemic pneumonia has been described in ten of the fourteen complete routine necropsy reports quoted by Gundry and Warner¹. It appears to be primarily a bronchopneumonia with a lobular type of involvement, often accompanied by areas of focal necrosis. Confluence of the lobules may lead to large areas of caseous consolidation, in which cavitation may be found if secondary infection is present.

Roentgen studies of tularemic pneumonia give results in accord with its known pathologic changes, but the diagnosis cannot be made by chest films alone. The pathologic process was followed in one patient (patient 34) dying on the sixteenth day after infection, by

From the Departments of Roentgenology and Internal Medicine, University of Virginia Hospital.

Read before the Section on Radiology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

¹ Gundry, L. P., and Warner, C. G.: Fatal Tularemia. Review of Autopsied Cases, with Report of a Fatal Case. *Ann. Int. Med.* 7: 837 (Jan.) 1934.

serial roentgenograms from the seventh to the fifteenth day. The first films revealed a great enlargement at the right hilus, which subsequently increased and was surrounded by pneumonic infiltration. Central necrosis in the hilus region was visible on films taken the day before death. An autopsy permit was refused in this case. In the other two fatal cases (cases 5 and 26), however, necropsy examination confirmed the roentgen interpretation of necrosis; one presented an area of central softening in the midst of an extensive pneumonia, and the other presented consolidation with multiple abscess formation. Three surviving patients gave roentgen evidence of infiltration without rarefaction, and these patients have been roentgenologically studied since recovery: one had practically no residual change six weeks later, one had a thickening of the bronchial tree after five months, and one had marked fibrosis after five years. Roentgenograms in the fourth surviving patient revealed definite pneumonia with what appeared to be central softening. Follow-up films could not be obtained in this case.

One of the necropsies (case 5) has been reported already in detail and a second one (case 26) will be reported elsewhere.

One illustrative report presents the salient features of pulmonary consolidation.

CASE 30—H. W., a Negro farmer, aged 19, picked up a dead rabbit, Aug. 24, 1933. Two days later there was a sudden onset of fever, headache and malaise. He was admitted, August 29, on account of a general toxic condition: fever of 103.6 F., vomiting abdominal pains and a slightly productive cough. The physical examination and laboratory studies were negative except for suppression of breath sounds and showers of moist rales in the left side of the chest, anteriorly. A pneumonic area from the second to the fifth rib on the left was seen in a roentgenogram (fig. 1) made August 31. Definite physical signs of pneumonia were found September 1. The patient became afebrile September 3. A routine agglutination test for tularemia was positive in a titer of 1 to 160 on September 4. Almost no residual change was discernible in chest films made on September 9. The patient was discharged on September 10. He returned by request on October 7 for further roentgen examination. There had been apparently some increase in the calcium deposit in the right hilus zone (fig. 2).

PERIBRONCHIAL THICKENING

The correlation between the tularemic necropsy material and the roentgen appearance of peribronchial thickening can be made only by deduction. The necropsy studies in tularemic pneumonia show that it is primarily lobular in type, which implies that the inflammatory process begins in and around the bronchi. If this process does not proceed to consolidation, the inflammatory changes should produce the picture of peribronchial thickening in roentgen films. This roentgenologic finding may represent bronchitis, peribronchitis, fibrosis or a combination of the three.

An uncomplicated increase in peribronchial markings was noted in the films in seven active cases (cases 3, 16, 17, 19, 27, 31 and 32) of this series. There was usually some haziness in addition to the thickening in these active cases, and it was thought to represent an acute bronchitis or peribronchitis rather than a simple fibrosis.

The report of one case with both clinical and roentgen evidence of bronchitis will suffice for illustration.

CASE 19—E. P., a Negro woman, aged 41, a housewife, skinned rabbits frequently during the fall of 1931. About November 25 she accidentally cut her right index finger, and

this was followed by a "waxing kernel in the armpit" and a "severe cold," the symptoms of which consisted of feverishness, chills, malaise, weakness, nasal discharge and a cough. Although she was quite sick, she did not go to bed. She came to the outpatient department, Jan. 11, 1932, complaining of axillary enlargement. A few rales and signs suggestive of consolidation were found in the right posterior hilus region. Tularemic agglutination, taken January 14, was reported positive in dilutions up to 1 to 640. Roentgen films (fig. 3) January 20 revealed thickening of the lung markings most marked in both hilus regions. No subsequent data could be obtained.

PLEURAL EFFUSION

Fluid in the pleural space has been reported in three of fourteen tularemic necropsies. Verbruyck mentioned the presence of 100 cc in each pleural cavity in association with pneumonia. Goodpasture and House found 200 cc in one pleural sac but discovered no evidence of intrapulmonary involvement. Bunker and Smith recorded finding 840 cc in one pleural cavity and noted that, in addition to pneumonic consolidation of this lung there were six or eight white areas on the surface, which did not extend into the lung substance. One of the fatal cases (case 26) of our series presented a probable pneumohydrothorax, with 400 cc of fluid. These observations prove that tularemia must be considered as a rare but possible cause of pleural effusions.

The roentgen examinations of the chests in our series were of no assistance in identifying the tularemic nature of the effusions. One case serves to illustrate.

CASE 35—S. H., a Negro schoolboy, aged 18 years, admitted to a hospital in Washington, Sept. 30, 1933, had a "cold" and pain in the right side of the chest of two weeks duration. There were definite signs of fluid in the right base and a thoracentesis removed fluid but there is no record of the amount or nature of this fluid. A roentgen film was taken just before his discharge, November 10, which was considered to be negative except for some thickening of the pleura on the right side. The boy returned to his home feeling somewhat weak and with a persistent cough but was otherwise in fairly good health until December 23 when he was suddenly awakened by a severe inspirational pain in the right side of the chest, which lasted off and on for about a week. His local physician made a diagnosis of pleurisy with effusion and kept him in bed until dyspnea and a temperature of 104.4 F. necessitated admission to this hospital, Jan. 4, 1934. Signs of a large amount of fluid in the left side of the chest were found on examination. The patient was greatly relieved by the removal of 500 cc of fluid, January 6. No acid-fast organisms could be stained. Guinea-pig inoculation was negative for tuberculosis. January 8, an additional 600 cc of fluid was aspirated. In view of the high fever with a low leukocyte count a diagnosis of tuberculous effusion seemed most likely even though several sputum examinations were negative for acid-fast organisms. A tularemic agglutination taken as a routine, January 9, was reported positive in dilutions of 1 to 320. January 11, 75 cc of fluid was removed and an unsuccessful effort made to recover *Bacterium tularensis* by animal inoculation and cultures of this fluid. However the fluid agglutinated the organism in dilutions of 1 to 160. Immediately after this aspiration anteroposterior (fig. 4) and lateral films were made, which showed a massive hydrothorax in the posterior portion of the left side of the chest. There was a slight haziness and increase in the lung markings of the right side of the chest. The patient was almost afebrile and practically free from symptoms at the time of his discharge, Jan. 14.

NODULAR INFILTRATION

Lesions of peribronchial and bronchial lymph nodes have been recorded in three of the fourteen tularemic necropsies. This glandular involvement may be independent of lesions in the lung, since in one instance no

It has already been mentioned that roentgenographic peribronchial thickening may represent bronchitis, peribronchitis fibrosis or a combination of the three factors. It was stated that the hazy appearance of the thickening present in the active cases was thought to be due primarily to bronchial and peribronchial inflammation. This hazy appearance was generally absent in the thickening seen in the patients who recovered and this was interpreted to mean that fibrosis largely accounted for the changes observed. The thickening was generalized in some cases and localized in others. In a few instances the fibrosis occurred in areas known to have been involved at the time of acute infection. Most of the localized areas were not apical. In the

Fig. 3—A case showing marked thickening of the trunk markings.

When no previous films are available for comparison it is obviously difficult to estimate an increase in calcium deposits following tularemia. One cannot be certain that extensive calcification as a result of tuberculous infection might not have antedated the tularemia infection. In one of the present cases an excessive amount of calcium was observed in a film taken so soon after the tularemia infection that tularemia could not have accounted for the deposits. On the other hand, calcification in this series generally appeared to be greatly out of proportion to that seen in comparable groups without tularemia, and in one instance (case 30) it was thought that a definite increase in calcium deposit could be noted in films taken six weeks after recovery. There are so many points of similarity in the body reaction to tuberculosis and tularemia that it would not be surprising to find that tularemia also produced calci-

fication in the lungs. This study can offer no conclusive proof to this effect, but the data are sufficiently suggestive to indicate the need for further observations.

There was an enormous enlargement in the superior mediastinum in one patient (patient 6) whose films were made five years after the tularemic infection. The appearance of this lesion was consistent with a malignant condition or of pulmonary syphilis, but the patient seemed in unusually good condition and would not submit to further diagnostic studies. In view of the fact that another patient (patient 18) has recently had suppuration from a tularemic gland three years after infection it may be that this mediastinal shadow represents persistent enlargement of tularemic glands and residual fibrosis.

The roentgen films of only two (patients 22 and 25) of the thirty-four patients were considered to be within the limits of normal.

SUMMARY

Definite pulmonary changes demonstrated by roentgen examination are present in a high percentage of cases of tularemia.

Fig. 4—Massive pleural effusion resulting from tularemia.

Fig. 5—Nodular infiltration in acute tularemia simulating the puerile type of tuberculosis.

The changes in the active cases are (1) pneumonia, with or without necrosis, (2) pleural effusion, (3) nodular infiltration, (4) peribronchial thickening.

The residual changes are (1) increased fibrosis, (2) an apparent increase in calcification.

Every atypical chest case occurring in tularemic territory should have the benefit of a diagnostic agglutination.

Distribution of Follicle Stimulating Factor and Luteinizing Principle—These hormones are present in varying degrees of concentration in different parts of the body, and especially in the anterior part of the pituitary gland of all mammals and the placenta of human beings and some mammals. It is also found in the urine under certain conditions which include pregnancy, after the menopause, hydatiform mole, chorionepithelioma, some cancers and the urine of men suffering from testicular teratomata. The injection of prolactin into sexually immature animals is rapidly followed by signs of activity in the genital organs, which display ripening of the graafian follicles, follicular hemorrhages and luteinization in the ovaries and hypertrophy in the walls of the uterus. All these changes are due to the action of this hormone upon the gonad and not to any direct effect upon the uterus because they do not occur in castrated animals. Hence prolactin is said to be gonadokinetic and not uterokinetic in function.—Robinson, A. L. and Datnow, M. M. *The Differential Diagnosis of Pregnancy*, *Lancet* 11 (Jan 5) 1935.

INTERPRETATION OF ROENTGENOGRAMS IN PULMONARY TUBERCULOSIS

HENRY K. TAYLOR, M.D.

NEW YORK

Serial roentgen studies of pathologic changes of superinfections and reinfections (secondary) in pulmonary tuberculosis reveal that the lesions are either exudative or productive in character from the earliest time that patients come under observation. These lesions have a tendency to heal. The end result of the healing manifestations in pulmonary tuberculosis, demonstrable on the roentgen film, permits of a division into five types.

The exudative lesion terminates in one of three ways: (1) It may completely resolve and leave no traces in the roentgenogram; (2) it may resolve and leave a residual of a few fibrotic strands; or (3) it may undergo caseation and cavity formation. The productive lesions present themselves in one of two forms:

- (1) fibrotic strands with small nodules and
- (2) fibrosis with numerous small cavitations resembling a bronchiectasis.

EXUDATIVE LESIONS

1 Complete Resolution—Early in the development of this lesion there are coalescent multilobular areas of decreased aeration varying in size from a small patch to a lobe or lung, an area of exudation or consolidation, and with it perhaps a certain amount of atelectasis (fig. 1). This completely resolves in from six weeks to six months, leaving no traces of the lesion in the roentgenogram. During resolution, annular shadows sometimes appear, which may be confused with cavities. These annular shadows are not true cavities and disappear as resolution progresses. True cavities, which close spontaneously, usually leave some evidences (of fibrosis) in the roentgenogram.

2 Resolution with Fibrosis—The roentgen changes are similar to the lesion described in the previous paragraph (fig. 2). Resolution takes place in from six to eighteen months, leaving a few fibrotic strands as a residue. Here also annular shadows resembling cavities may present themselves, disappearing as resolution progresses.

3 Caseation and Cavity Formation—The lesion may be small or large. In the early stages it resembles the lesions just described. Nature's attempt at healing is to localize the lesion and expel the products of the infection. The result is caseation with cavity formation in a comparatively short time (fig. 3). Cavities serve as constant sources of tubercle bacilli. Superinfections to other portions of the lungs may occur. This caseating lesion may terminate in two ways: (1) It may completely excavate itself and leave one (fig. 4A) or more cavities; or (2), after excavation, the involved lobe or lung may retract, causing deformities—deviation of the trachea, heart, mediastinum, retraction.

Read before the Section on Radiology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.

tion of the chest wall and the like, all to the affected side (fig 4B). Pleural thickening also assists in producing deformities.

PRODUCTIVE LESIONS

1 *Fibrosis with Nodules*—This type is not preceded by a demonstrable exudative lesion. On the roentgenogram are found small dense nodular shadows interspersed with fibrous strands (fig 5A). The lesion is very often bilateral. It may be limited to the apices

Fig 1—E. L. a white girl aged 17 years. A small coalescent exudative lesion in right infraclavicular area Dec 17 1927. B two months later complete resolution with no trace in the roentgenogram Feb 14 1928.

or upper lobes, remain stationary, or progress slowly and eventually result in extensive involvement of the lungs.

2 *Fibrosis with Small Cavitations*—At times the nodular lesions in the previous type coalesce, caseate and produce small cavities (fig 5B). Following this, small miliary foci may develop adjacent to the lesion. A gradual extension of the lesion may occur by frequent bronchogenic spreads.

The types described here are not serial changes of one lesion. They all represent pulmonary tuberculosis. Clinically as well as roentgenologically, each type runs its own characteristic course, showing changes that are peculiar to it.

The exudative lesion that caseates and forms cavities shows many varieties combinations of excavation, exudation, fibrosis, deformities and the like. These changes are incidental to this type and because of these various stages of this one lesion, have fallen heir to many names, such as chronic ulcerative fibrocaceous ulcerocaceous and mixed cavernous lesions.

As mentioned in the beginning of this paper, the healing manifestations determine the type of lesion. Superinfections in my experience, show no roentgen evidences of healing by calcification. If it does occur it is exceedingly rare. The healing manifestation of the primary infection is resolution with a residue of one or more calcareous foci. The dissemination attending or immediately following the primary infection may heal by calcification.

Miliary tuberculosis is not included in the types described, for it is an accidental rupture of a caseating focus into the blood. This accident develops into a local or a generalized miliary tuberculosis. The liberation and wide dissemination of many organisms result in a generalized miliary tuberculosis with a fatal outcome in a comparatively short time (fig 6A). When few organisms are released from a caseating focus,

they may develop miliary lesions wherever arrested. At times, a caseating focus may discharge at intervals. There are then crops of tubercles appearing with each discharge of organisms. In the lungs, the manifestations of an intermittent hematogenous spread show discrete and conglomerate tubercles of varying sizes (fig 6B). In the beginning, the area involved is not great but with each succeeding discharge of organisms more and more lung structure becomes involved. In two patients I have seen such miliary lesions resolve leaving no traces in the roentgenogram. A bronchogenic spread of the infection either from a cavity or from a ruptured caseating tracheobronchial lymph node sometimes resembles a miliary tuberculosis (fig 6C). Often it is an acinous spread of a benign nature eventually disappearing.

From this brief description it is apparent that the roentgenographic study of the pathologic changes in tuberculosis reveals a qualitative as well as a quantitative component. An evaluation of the quantitative component resulted in the National Tuberculosis Classification: minimal, moderate and extensive, modified by A, B, C and so on. An evaluation of the qualitative component demands some other designation to the lesion.¹ That this has occurred to others, the evaluation of the qualitative component is quite evident when one examines the literature. Many classifications have been offered. Most classifications depend on autopsy material without serial roentgenographic correlation. The autopsy material presents the terminal stage of the disease giving no information as to progression or intermediate stages.

This presentation is a modification of the clinical classification of Ornstein, Ulmar and Dittler.³ They used the terms benign-exudative, exudative-productive

Fig 2—L. H. F. a Negro youth aged 15 years. A coalescent exudative lesions in right upper lobe and central portion of the left lung Nov. 29 1931. B resolution of exudative lesions with residual of fibrotic strands Jan. 16 1934.

chronic-proliferative and caseous-pneumonic. While these terms are satisfactory they are also confusing. They portray a pathologic state rather than a clinical impression. These authors are now dividing all their

1 In addition to the qualitative element of the lesion the anatomic description as well as the quantitative component may be utilized. The lesions may be acinous, lobular, multilobular or lobar, discrete or coalescent, local or general, unilateral or bilateral, minimal, moderate or extensive.

3 Ornstein G. G. Ulmar David and Dittler E. L. Benign Acute Pulmonary Tuberculosis. Am. Rev. Tuberc. 23: 223-247 (March) 1931. A Clinical Classification of Pulmonary Tuberculosis. ibid. 23: 248-285 (March) 1931.

cases into exudative and productive lesions⁴. The exudative lesions may (1) resolve quickly, (2) resolve slowly or (3) show no resolution. In 1931 Shipman⁵ independently presented a clinical classification which closely resembled that of Ornstein Ulmar and Dittler.

COMMENT

From a clinical standpoint, with the aid of the roentgen study all cases of pulmonary tuberculosis can be divided into two groups. One group has practically

Fig 3—K M a Negro youth aged 19 with tuberculous arthritis of the left elbow. A routine examination of the chest showed no pulmonary tuberculosis April 28 1933. B coalescent exudative lesion in the right upper lobe December 8 C four months later the lesion is almost completely sloughed away leaving a large cavity April 13 1934.

no mortality rate and can be considered benign, the other has a high mortality rate and should be considered malignant.

The benign lesions run mild clinical courses. Their prognosis is good and requires no active intervention such as collapse therapy measures. The malignant lesions usually run a stormy course, often metastasize

Benign

Exudative — complete resolution
— resolution with residual fibrotic strands.

Productive — stationary
— slowly progressive.

Malignant

Exudative—cavitation — without deformity
— with deformity

Productive—coalescence of nodules with cavity formation

and spread. These are the only types that compel the use of collapse therapy measures. The prognosis in the untreated case is bad.

The pathologic mutations observed in serial roentgenograms reveal whether a lesion is benign or malignant. This information aids in determining prognosis and treatment. A malignant lesion may be superimposed on a benign lesion by a reinfection or superinfection. In the productive lesions, when the nodules coalesce, caseate and produce cavities, the lesion should be considered malignant.

The foregoing graphic presentation of the various types of tuberculosis summarizes the correlation between the clinical and the roentgenologic changes.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs ARCHER, BLACKFORD AND WISSLER
AND DR TAYLOR

DR L R SANTE St Louis. It is hazardous to attempt the diagnosis of any radiologic study without full consideration of the clinical history. The paper of Drs Archer, Blackford and Wissler brought out that there is a much more widespread involvement of the pulmonary tissues in tularemia than was formerly suspected. Their work seems to point out that the infection is primarily a septicemia which extends to the lung

at times producing lung destruction with pleural effusion, depending on the extent and severity of the infection. The residual fibrosis referred to in these cases is perhaps nothing more than one would expect when large areas of lung tissue were involved. In one instance in which bronchial development was found, the patient recovered and remained normal without evidence of residual fibrosis for two years but now I understand that he is again having lung trouble. The closest consideration should be given to the possibility of the healing of tularemia lesions by a calcium deposit. Up to the present it has been generally accepted that healing by calcification is considered evidence of a tuberculous cause of the primary infection, that

is, that tuberculosis heals by calcification. I think therefore that one must be very careful in stating that tularemia also heals with calcification unless one has undisputable evidence. In Dr Taylor's paper the division into benign and malignant types of tuberculosis after following the cases through to the end result is a more or less simple matter and seems to me a very interesting study. When one attempts to apply it to new cases however in an endeavor to estimate the prognosis that is another matter. I doubt whether it will be possible to predict what is going to happen in any case of pulmonary tuberculosis there are too many complicating factors involved.

DR KENNON DUNHAM Cincinnati. This symposium in one way or another brings out the necessity for clinical consideration as well as roentgen study. The papers stress the necessity

Fig 4—A A H a white woman aged 34. Lungs show cavities no deformities two year history. B J C a white woman aged 36. Retraction of right side of the chest and lung with deviation of trachea heart and mediastinum to right three year history.

for consultation. In other words, the radiologist should be a consultant and not a technician. Dr Sante has stressed history taking and I wish to emphasize consultation. Few radiologists will make good physical examinations or take good histories but they can learn much from men who do and they will teach those who do not. Our patients must be our first care. These papers show that consultation is necessary, because the clinical aspect must be considered and this will lead to further roentgen studies. Pulmonary tuberculosis is an infection and must be so

considered. The fun type is a lobular pneumonia. The bronchogenic spread produces bronchiopneumonia, and the acute infection involving the greater part of a lobe is a lobular pneumonia. As in other pulmonary infection there are absorption and repair (scar tissue) and breaking down (abscess). I warn against a too fine classification especially against diagnosing a benign type of pulmonary tuberculous inflammation. Some infections show much more virulence than others but this is common to all inflammations. I urge caution. My experience does not justify cocksureness. I have seen very few cases of pulmonary exudate due to tuberculosis that were benign. They may clear

Fig 5—4 D R a white man aged 24. Numerous small nodules in the upper lobes eight year history. B M C a Negro man aged 37. Fibrosis with numerous small cavitations in the upper lobes ten year history.

up for a time but they have a nasty way of returning. When such cases are noted one should look for a focus of tuberculosis in some other part of the body such as surgical tuberculosis or a lymph node infection. These patients need great care after the lung has cleared. Humility and consultation are the watchwords in dealing with pulmonary inflammation. Physicians cannot know enough and therefore must tread lightly with all the knowledge at their command.

DR EUGENE P. PENDERGRASS Philadelphia. I think that in certain communities a routine agglutination test for tularemia in unexplained chest lesions is to be encouraged and I feel quite sure that this accounts for the large number of cases that Drs Archer, Blackford and Wissler reported. It has always seemed to me that a radiologist should approach a diagnostic problem by asking himself just what conditions could cause the appearance seen on the roentgenogram. The possibilities could be suggested to the clinician referring the patient and further efforts made to differentiate the lesion by approved clinical methods. In the Archer, Blackford and Wissler report the cases of tularemia could simulate any one of several conditions such as lymphomas, tuberculosis of childhood or adult influenza, Friedländer's pneumonia, mycotic infections, fusospirillary disease, sporotrichosis, spirochetosis, and possibly other things that I have not mentioned. The unusual feature of this infection is the possible deposition of calcium in a healing or healed lesion. There must be other infections besides tuberculosis that will cause calcification and healing but it has been taught so long that calcification in a lesion usually means a healed or healing tuberculous process that it behooves one to be careful. Dr Taylor's plan of grouping cases is of value for short time supervision provided the patients are examined at regular intervals and the other indications (sedimentation test, white blood count, volume

and quality of the sputum and temperature) are not disregarded. I have become impressed with the fact that grouping is all right for the immediate case but does not work satisfactorily when the study is carried over a period of years. Benign exudative lesions may interchange with benign productive lesions or benign productive (slowly progressive) with malignant exudative lesions with cavitation. As a rule, the true proliferative or productive lesion is seen in adults from 30 years up and these lesions are liable to remain constant. Lesions in adolescence may do anything. They are very unstable and I believe it is unsafe to group them as benign or malignant. I have had an opportunity to study the films of some of Dr McPhedran's patients, and it is safe to predict that many radiologists would be surprised to see what a so-called benign lesion developed into. Because of these cases, I should hesitate to accept Dr Taylor's ideas as to prognosis. Dr Taylor refers to annular shadows. I would strongly recommend rotated films to determine whether an annular shadow is a cavity or not. There are many cases in which it is impossible to distinguish between annular shadows and cavities in good stereoscopic films. Cavities close to the hilus posteriorly are often missed in the postero-anterior view. Dr Taylor states that superinfections do not heal by calcification. I should like to ask whether he means hematogenous or bronchogenic exogenous or endogenous infections.

DR JAMES L. DUBROW, Des Moines, Iowa. It is unsafe to diagnose pulmonary lesions as benign or malignant from the roentgenographic appearance alone. The basis for etiologic diagnosis is correlation of clinical with laboratory observations.

DR G. E. PFAHLER Philadelphia. The fact must not be lost sight of that tuberculosis and carcinoma can exist jointly in the same case, which means that the finding of tubercle bacilli doesn't rule out cancer. Likewise to emphasize what has already been said here one must not be satisfied always that a final diagnosis can be made at a single examination.

DR HYMAN I. SPECTOR St. Louis. I just want to make one remark and that is that at times an attempt is made to differentiate an interlobar effusion from a malignant condition or a tumor. I remember two such cases in which the clinical signs and symptoms were those of a malignant growth but the x-ray shadow looked more like an effusion. At necropsy both effusions and malignant growths were found.

DR HENRY K. TAYLOR New York. I am not changing the concept of the pathology of pulmonary tuberculosis but presenting it from a slightly different point of view. I have deliberately omitted the clinical aspect from this paper and therefore shall not discuss the various clinical points raised. While I

Fig 6—4 J Z a white man aged 31 admitted May 26 1932. One year before a tuberculous cervical gland was excised and drained for five months. In April he had complained of weakness, fever, cough, expectoration, anorexia and loss of weight. A roentgenogram June 8 showed miliary tuberculosis. He died July 7. Autopsy showed generalized miliary tuberculosis. B H W a Negro man aged 24 admitted Nov 17 1933. A cervical gland had been excised three years before. Present illness started three months before admission with cough. Two months later enlargement of the abdomen. A roentgenogram November 20 showed few small acinous exudative lesions in the lower lobes. These lesions increased in size and number until the lungs were completely involved December 26. He died Jan 10 1934. Autopsy showed miliary lesions in the lungs, peritoneum, spleen, adrenals, prostate and pancreas. C T De L a white man aged 39. Bronchogenic spread from cavity in the left apex.

consider the roentgen examination only an aid to the clinician, the clinician will not and should not undertake to diagnose and treat without serial roentgen examinations of the chest. This presentation is based on serial examinations, clinical as well as roentgenologic. The conclusions drawn from this study are

summations at the end of the whole study. The problem now is to apply one's observations profitably while the patient is alive, and it can be done. At no time during the observation of a patient is a definite diagnosis made or prognosis given from the first or second examination, or from any single examination, unless it is recognized as a caseating lesion. I have seen many exudative lesions disappear without collapse therapy measures. If, in a benign exudative lesion or a pneumothorax, should be induced or a phrenicectomy performed, either measure would receive credit for the cure of a lesion that would disappear with bed rest alone. Dr. Dunham mentioned that he does not see cases presenting benign lesions. The benign lesion is not new. The literature contains many case reports of benign lesions. The benign lesion probably occurs more often than one suspects but it is overlooked, for the clinical symptoms are mild, being no more severe than an ordinary cold, and roentgen examinations are not usually made. I have seen caseating lesions, collapsed early, not completely sloughed out, continue to caseate under pneumothorax. Dr. Pendergrass asserts that there is an interchange of lesions. Various types may appear in one individual, these are not serial changes of a lesion. Superinfections do vary. A so-called interchange of the lesion may be a spill. The course of a spill cannot be predicted at the onset. It may assume characteristics of any type described. I have not observed superinfections, adult type lesions, heal by calcification. Recently, Pinner stated that some hematogenous spreads heal by calcification. Several years ago Miller commented on the difficulty of actually determining calcification in the roentgenogram. If any one can show me pulmonary roentgenograms devoid of calcareous deposits before a lesion appears, the same cases with subsequent tuberculous lesions, and calcareous deposits after the lesions heal, I will accept the statement that tuberculous lesions heal by calcification. Until then I will concede its possibility and then only as a rarity.

DISLOCATIONS OF THE CERVICAL SPINE

SOME PREDISPOSING CAUSES

THEODORE PREWITT BROOKES, M.D.
ST. LOUIS

Reviewing a series of sixty-five of my own cases of traumatic dislocations of the neck, seen during the last six years, I am impressed with the presence of systemic predisposing causes in a certain small group. From a mechanical point of view, the more obvious offenders are stairways and automobiles, constituting twenty-one cases, or one third of the total. As a toxic predisposition, of course alcoholism heads the list, being definitely present in six cases and presumably responsible in several more.

Among destructive bone conditions, tuberculosis and osteo-arthritis of the cervical spine must be classified as direct causative factors and are not included in a study of traumatic dislocations. The possible existence of such lesions must be kept in mind. I have seen one dislocation of the cervical spine reduced, only to find by later developments that it was in reality an early case of cervical Pott's disease.

DISLOCATION DURING ILLNESS

Three cases developed in adults during treatment of other conditions. One was under the care of regular physicians, while the other two were seen by cultists. The former, case 17, showed severe rotary dislocation of the atlas after a siege of some weeks with peritonsillar abscess, tonsillectomy and adenitis. This was

overlooked by several attending physicians in different communities, apparently by reason of infection in the neck. The lesion was eventually recognized and reduced some nine months after its occurrence.¹ It is a question whether or not this was one of the interesting group of nontraumatic dislocations described by Berkheiser and Seidler.² I am inclined to believe that it belongs to the group with weakened soft tissues, permitting dislocation with a minimum of violence. Such a case, occurring in the practice of Dr. F. H. Albee, was reported by Mixer and Osgood.³

MANIPULATIVE DISLOCATIONS

One of my own patients and one seen with Dr. F. A. Jostes suffered rotary dislocation of the atlas during treatment by cultists for painful muscles in the neck or chest. The former, case 40, presented a muscle strain and the latter, case 61, a myalgia of the neck with a "cold in the head." Each patient had received violent manipulation of the neck by cultists. Patient 40 suffered bilateral dislocation of the atlas, while patient 61 had marked rotation and unilateral dislocation of the atlas. The manipulators might maintain that the subluxation existed prior to the treatment and persisted by reason of the patient's failure to continue the "course of adjustments." However, such is not the history. The first patient received no definitive treatment of his dislocation for an entire year. The second man waited three weeks before consulting a competent physician. When he learned his ailment he refused for weeks to permit reduction, preferring to retain his displacement to use as an "exhibit" during legal proceedings against the cultist. A dozen such manipulative dislocations of the atlas came to light through the presentation of Blaine's paper before the American Medical Association in 1925.⁴ On the other hand, one of our cases had been recognized by a cultist and referred to a competent surgeon after being inadequately handled by former medical attendants.

DISLOCATION DURING PRODROMES OF DISEASE

A more subtle preliminary to dislocation is seen in the prodromal stage of acute illness. This has proved confusing in five cases. A child does some awkward thing and then falls. Discomfort and complaint are no more than are to be expected from a fall. The next day the youngster is found to be suffering with an acute infectious disease and remains in bed. On recovery from the illness a wry neck is noted and assumed to be toxic in origin. It is only after failure of expectant treatment that more careful examination reveals an actual dislocation of one of the vertebrae. The conclusion is forced on me that during the prodromal stage of an illness the youngster is more or less cranky and restless, probably even less sure footed than usual and does some bizarre climbing or tumbling about that even his juvenile judgment would veto under normal circumstances. It is also probable that the tissues of the neck are less resistant to strains and pulls, permitting displacement with less than the usually required trauma.

DIFFERENTIAL DIAGNOSIS

In earlier papers attention has been called to the frequency with which so-called simple rotary dislocations of the spine are overlooked. In injuries occurring during acute illnesses there is reason for attributing the condition to a toxic torticollis but no adequate excuse for faulty diagnosis. In toxic wry-neck, the head is rotated and held down on one side by a spastic, shortened sternocleidomastoid muscle. Movement in any direction is painful, much more so than in dislocation, and constant. The deformity becomes corrected as the condition subsides. In rotary dislocation the head is twisted and held down by a bony block. The shortened sternocleidomastoid muscle on the down side of the head is soft and flaccid, while the corresponding muscle on the upward side of the rotated neck is taut and prominent. A certain amount of motion is easily made in the direction of displacement, while efforts to rotate the head in the direction of correction cause pain or are stopped by a sense of mechanical block at the site of dislocation. The deformity becomes more noticeable as atrophy of dis-

In the latter cases of the series much help has been given by Dr Sherwood Moore and his associates Dr Hugh M Wilson and Dr T S Jung, operating the fluoroscopic unit in the Mallinckrodt Institute of Radiology. Incomplete reduction and even overcorrection have been demonstrated on occasions. It was then possible to replace accurately the dislocations while still under observation and apply the cuirass with the assurance that a second plaster would not be necessary as soon as films were made.

TECHNIC OF REDUCTION

Figures 6 and 7 show the adaptation of the Taylor⁵ technic in this series. It has been used in the bilateral dislocations and in dislocations with known fracture complications. The Walton⁶ technic has been used in the majority of unilateral simple dislocations. Some cases have required repeated use of both methods. In either technic the operator must be thoroughly familiar with the planned procedure for the particular case. Accurate diagnosis is the first requisite. He will then make a careful review of the articulated cervical spine

Fig 1 (case 58)—Lateral. Extreme fracture dislocation without cord symptoms. Fracture extends through both laminae of the axis permitting the body of this vertebra to be displaced downward in front of the body of the compressed third cervical. The posterior margin of the body of the second caught on the anterior margin of the crushed third stopping further angling and fracture of the cord. The odontoid held to the ring of the atlas and the body of the axis as the latter broke away from the laminae thus saving the cord from laceration.

Fig 2 (case 58)—Roentgen appearance through plaster-of-paris cuirass after reduction. Normal cervical curve has been restored. Body and laminae of the axis are in approximation. Fragments of the third vertebra in satisfactory alignment. Two buckles appearing on the print are in the Sayre head sling which was used during the Taylor technic of reduction. The head sling was also used to hold neck in hyperextension during application of the cast (fig 7). It will not be removed until the cast is removed or changed.

Fig 3 (case 58)—Appearance three months following reduction. Fracture through the laminae of the axis has healed completely. The ventral face of the third is in apposition with and united to the body of the vertebra. Compression of the body of the third is satisfactorily expanded and shows bone regeneration. There is slight tilting of the second which cannot be improved.

use develops in the tissues thrown out of commission on the down side of the neck.

ROENTGENOLOGIC AID

Roentgenograms, accurately taken and carefully interpreted, will verify the clinical observations in the majority of instances. Inability to demonstrate the dislocation in the roentgenograms should not however, settle the diagnosis in the doctor's mind. Despite the remarkable development of technic and knowledge in the field of roentgenology, lesser dislocations or subluxations cannot always be shown conclusively on the films. This is especially true in the region of the atlas and axis. Routine roentgenograms call for three exposures: lateral of the cervical spine and two anteroposterior views, of which one is taken through the open mouth to show the first two vertebrae. Frequently, additional oblique views are required to show the articular processes

as well as of the literature on the subject. A fair proportion of recent, uncomplicated cases may be reduced without anesthesia. I feel that cases of long standing, cases with fracture complications, and cases of severe extent can be better handled under general anesthesia. Redislocation occurs too often in cases in which temporizing methods have been used with failure to secure full correction and accurate reseating of the articular processes. Such failure may also be due to delay in reduction with development of changes in intervertebral joints or irreparable damage to the articular capsule. During the preparation of this paper patient 55 has returned, with redislocation six months after

5 Taylor A. S. Fracture Dislocation of the Neck. A Method of Treatment. *Arch Neurol & Psychiat.* 12: 625-639 (Dec.) 1924. Fracture Dislocation of the Cervical Spine. *Ann Surg.* 90: 321-340 (Sept.) 1929.

successful reduction. It is believed that the capsule or ligaments were torn severely. Open operation was resorted to, the method described by Mixer⁷ as amplified by Jackson⁸ being used. The surgical procedure was not to reduce the dislocation but to maintain the

CASE 9 (previously reported⁹)—R. W., a girl, aged 6 years while playing at home one evening fell over a chair hurting her neck and leg. The next morning she had the mumps and spent two weeks in bed. On getting up she was found to have a wryneck. She was treated several weeks by several physicians, including myself, for toxic myositis. Additional roentgenograms compared with the original films led to the correct diagnosis of rotary dislocation of the third cervical vertebra. This was reduced four months after the injury.

CASE 39 (previously reported¹⁰)—A. R., a girl, aged 8 years, after a fall in the school yard, had a wryneck that disabled her. A short time later, 'German measles' developed and she was taken to the Contagious Disease Hospital. There the correct diagnosis of traumatic dislocation was made, but for some reason she continued to be treated by a number of physicians and cultists for various alleged conditions. The history is confusing as to the exact length of time between the injury and the appearance of the rubella but there is no question that the infection was credited by several persons with causing the wryneck. Severe rotary dislocation of the atlas was successfully reduced three months after injury.

CASE 43—R. McG., a white boy, aged 4 years placed a chair atop a small table and climbed into it. He fell to the floor. The neck was crooked the condition becoming more noticeable forty-eight hours later at which time a left submaxillary adenopathy developed. He was treated for septic adenitis for nearly three weeks. As the fever and inflamed glands subsided, Dr. Adrian Bleyer recognized the traumatic nature of the displacement and asked for orthopedic consultation.

Examination showed that the head was tilted to the left and that the chin was rotated to the right of the midline. The child could rotate the chin still farther to the right but he came to an abrupt stop at the midline in an effort to rotate it to the left. Films taken at

Fig. 4 (case 58)—Degree of hyperextension in plaster cuirass found necessary to maintain reduction in this particular instance, taken two months after injury. Patient comfortable and ambulatory.

Fig. 5 (case 58)—Celluloid doll collar applied after four months in plaster casts.

replacement. Reduction by the Taylor technic was first done, and a plaster cuirass was applied and bivalved. Three days later a heavy strand of braided silk was passed through the posterior ring of the atlas and tied to the spinous process of the axis. The success of the operation is not yet determined. I believe that it is applicable only to the atlanto-axial recurrent dislocations. The chances of successful reduction by open surgical approach are too doubtful to warrant their use except after all other means have failed and repeated displacements have recurred. The questionable value of open reduction in the neck has been well brought out by Taylor⁶ and latterly by Towne.⁵

ILLUSTRATIVE CASES

CASE 2 (previously reported⁹)—E. W., a white man, aged 36, fell down some steps and was immediately brought to the City Hospital, unconscious. On regaining consciousness he complained of pain in the neck. Roentgen examination showed anterior dislocation of the first cervical vertebra. He had an unexplained elevation of temperature for nearly three weeks apparently due to a respiratory tract infection. This was one of the earlier cases in the series and was treated by head traction over the head of the bed without results. Reduction was done by the Walton⁶ manipulation three weeks after injury. It is believed that the fall followed dizziness associated with the invasion by an acute infection of the respiratory tract. Owing to the delay, the reduction was not anatomically perfect though clinically satisfactory.

Fig. 6—Adaptation of Taylor technic in the Department of Operative Fluoroscopy of the Mallinckrodt Institute of Radiology, Washington University School of Medicine. Any stationary table is used. Counter traction is secured by crossed shoulder straps of muslin. Ends of these may be held by assistants or fastened to the table. Traction is applied with a Sayre head sling attached to a belt about the operator's waist. His hands are free to manipulate the head and neck. The roentgenologic unit is set up behind the table. A fluoroscopic screen is ready to be moved into position.

the Mallinckrodt Institute of Radiology by Dr. Sherwood Moore showed anterior luxation and rotation of the second cervical vertebra (fig. 8). Four weeks after injury, the dislocation was

reduced under nitrous oxide oxygen anesthesia at the St. Louis Children's Hospital the Walton technic being used. A plaster-of-paris cuirass was applied. Reduction was verified by roentgen examination. The cast was worn for three weeks after which a Thomas collar was worn for two months. Routine physical therapy was employed during this time. Complete recovery occurred, with full use of the neck.

Fig 7—After fluoroscopic verification of reduction the patient and the underlying steel strip are pushed off the table as far as the patient's waist. Cephalad end of steel strip is supported on a length of gas pipe set in a floor flange. When forceful hyperextension is indicated traction is maintained during application of plaster. The shoulder straps have been cut away in the illustration and the patient is being steadied by traction on the wrists. The head sling may remain until the cast is removed, or special clips may be used to permit unlocking and removal of the sling after the cast has set.

CASE 53—B O'B a Negro man aged 54 seen Aug 17 1933, at City Hospital No 2 through the courtesy of Dr Franklin Walton and Dr H E Hampton had two days previously been seated in an open window. He became suddenly dizzy and pitched out of the window, landing on his head some 15 feet below. He complained of pain in the back of his neck. Motion of the neck was possible through a limited arc. No gross neurologic changes were noted. Roentgenograms by Dr E W Spitzig showed an interesting and unusual double dislocation of the cervical spine (fig 9). The first five vertebrae were displaced forward on the sixth until the articular processes of the fifth were caught in the intervertebral notch anterior to the articular facets of the sixth and rested on the pedicles of the sixth. A second dislocation existed between the seventh cervical and the first thoracic vertebrae, the sixth and seventh being displaced anteriorly for a distance of one fourth of the depth of the vertebral body. August 18 under ether anesthesia the Taylor technic secured complete reduction, verified by roentgenograms. The patient remained unconscious however after the anesthetic. Reflexes were completely abolished and the patient died forty-eight hours later. Autopsy by Dr D L Harris revealed marked arteriosclerosis of the brain with softening of the left lateral lobe above the occipital area due to thrombosis of the posterior branch of the middle cerebral artery. An area of softening a week old was present. Evidently the first symptom of thrombosis was dizziness, resulting in the fall and dislocation of the neck. The area of softening was in a silent area of the brain and gave no gross neurologic signs at first but later caused death.

CASE 58—V M a white girl aged 16 years, was pitched out on her head during a collision between two automobiles. The case is reported and figures 1 to 3 are shown to illustrate the consecutive steps in the case of a severe injury of this character. At the City Hospital she was found to have fracture dislocation of the first second and third cervical vertebrae, fracture of the superior maxilla and Colles' fracture of the

left wrist. Thirty-six hours after injury, fracture dislocation of the neck was reduced by the Taylor technic and a plaster cuirass applied. Roentgenograms by Dr LeRoy Sante showed the position to be fair but not perfect. Manipulation under anesthesia was again done a week later. This time roentgenograms showed good replacement. A close check up was necessary as the tendency was for the second vertebra to slip down in front of the compressed and deformed third. Full hyperextension in the cuirass was maintained for sixteen weeks. A celluloid 'doll collar' was then applied, to be worn during the

Classification of Sixty-Five Dislocations

Deaths from injury	2
Redislocations requiring repetition of reduction	6

remainder of the year following the injury. The patient has good range of motion and roentgenograms show firm union with good position.

CONCLUSIONS

Stairways, automobiles and alcoholism are obvious predisposing causes of traumatic dislocations of the neck. In adults, an approaching illness may precipitate a fall and dislocation. In children, restlessness and irritability are frequently unrecognized prodromes of an acute infectious disease. A fall during such a prodromal stage may more easily produce dislocation of

Fig 8 (case 43)—R McG a boy with toxic adenitis. Forward slipping of the body of the second cervical vertebra. Rotation and tilting of the first and second vertebrae are evident from the obliquity of the posterior rings.

Fig 9 (case 53)—B O'B an adult with thrombosis of the middle cerebral artery. Double dislocation. There is clearly shown a bilateral dislocation of the fifth. The inferior articular processes are caught in front of the superior articular processes of the underlying sixth. In addition there is definite though less marked anterior dislocation of the seventh cervical on the first thoracic vertebra.

the upper cervical vertebrae by reason

of the impairment of ligaments and other restraining tissues. Development of the impending infectious disease confuses the clinical picture and has led in a number of cases to the erroneous diagnosis of toxic torticollis.

PEPTIC ESOPHAGITIS—WINKELSTEIN

JOUR. A. M. A.
MARCH 16 1935

ABSTRACT OF DISCUSSION
Dr R. D. SCHROCK, Omaha I should like to add another tissue showed "acute and chronic inflammation" The patient was treated with olive oil before meals, an ulcer diet, alkalis and atropine After one month he lost his symptoms and remained well for six months The symptoms both of the ulcer and of the esophagitis then returned. He also complained of "heartburn" and constant burning pain under the lower part of the sternum Again his symptoms disappeared on ulcer therapy The roentgenogram of the esophagus then became normal but the irregular duodenal bulb persisted. He has now been well for fourteen months Fractional test meals taken during the attacks showed marked hyperchlorhydria

CASE 2—W R, a man, aged 56 suffered from an acute perforation of a duodenal ulcer after seven years of peptic ulcer symptoms, viz, pain and heartburn three hours after meals relieved by food and alkalis Following the gastrotomy operation marked esophageal symptoms set in He complained of dysphagia inability to swallow solids, and pain under the lower part of the sternum After several weeks of these symptoms he was examined at the clinic A large stomach tube met an obstruction at 14 inches Radiography showed an irregular dilated and spasm of the lower part of the esophagus with inflamed mucosa at 35 cm Esophagoscopy showed a swollen and chronic inflammation" A biopsy specimen revealed "acute and so severe that three months after the perforation a partial gastrectomy was done by Dr A. A. Berg The resected antrum and duodenum in addition to the ulcer was also the site of a severe gastritis and duodenitis After this operation the esophageal symptoms grew steadily worse. The large stomach tube met an obstruction at 14 inches Radiography revealed spasm and irregular narrowing of the lower third of the esophagus Esophagoscopy showed narrowing intense congestion and a granular appearance of the mucosa, 34 cm from the mouth The biopsy specimen was reported as "acute purulent intragastric for peptic ulcer, viz, a continuous alkalized inflammation (fig 3) He was treated in the hospital with a special therapy for peptic ulcer, viz, a continuous alkalized intragastric milk drip through the Rehfuß tube His symptoms improved rapidly and he gained weight between 80 and 90) and moderate after the operation (from 30 to 40)

CASE 3—L A, a man aged 57 because of dysphagia obstruction at the cardia by stomach tube radiography and loss of weight was told five years before admission to the hospital that he had carcinoma of the esophagus He complained of dysphagia lower substernal pain radiating through to the back heartburn inability to swallow solids and sour regurgitation The course of his illness was a chronic one with exacerbations and remissions for five years Esophagoscopy by the late Dr Sydney Yankauer revealed a small punched-out ulcer 1.5 cm above the cardia Radiography showed irregular spasm of the lower part of the esophagus (fig 4) The biopsy specimen was reported "acute and chronic epithelial and subepithelial inflammation A fractional test meal showed a marked hyperchlorhydria (100 free acidity) With antacids and a bland diet he has had three similar attacks In the last two and a half years he has had three similar attacks In the lower third of the esophagus Esophagoscopy then revealed evidence of inflammation without ulceration and a biopsy specimen was reported acute and chronic inflammation" Between the attacks his general health has been excellent

CASE 4—S W, a man aged 61 complained of epigastric pain two hours after meals relieved by food and alkalis and that his food would "stick" under the lower part of the sternum Because of this symptom his age and a loss of weight in six weeks of 12 pounds (54 Kg), a carcinoma was suspected. The large stomach tube met an obstruction at 17 inches A test meal showed marked hyperchlorhydria (90 free acidity) Radiography revealed an irregular narrowing of the lower part of the esophagus and also some irregularity on the adjacent lesser curvature (fig 5) Esophagoscopy revealed an inflamed mucosa and the biopsy specimen was reported "acute

PEPTIC ESOPHAGITIS

A NEW CLINICAL ENTITY
ASHER WINKELSTEIN, MD
NEW YORK

The causes of esophagitis are usually given as follows

- 1 Irritative (mechanical thermal and chemical irritants including alcohol and tobacco)
- 2 Specific (syphilis, tuberculosis actinomycosis)
- 3 Secondary as a complication of (a) cardiospasm, (b) diverticula or (c) neoplasms

Recently I have observed some patients with a type of esophagitis that does not seem to fit into this classification The features of these cases are so distinctive as to impress one with the probability that they form a separate clinical entity They are, therefore, presented for consideration

REPORT OF CASES

CASE 1—S P a man aged 77 for three years had complained of typical symptoms of duodenal ulcer, viz late hunger pains some nausea and sour vomiting He presented a deformed duodenal bulb radiographically This attack was relieved by a Sippy regimen Three months later the symptoms of duodenal ulcer returned In addition he complained of dysphagia with lower substernal pain after meals A large stomach tube met an obstruction at the lower end of the esophagus An esophageal neoplasm was suspected Radiography revealed a markedly irregular narrowing of the lower third of the esophagus without any dilatation above (fig 1) Esophagoscopy by Dr Rudolph Kramer showed inflammation of the lower 3 inches of the esophagus A biopsy was performed and the

From the Medical Department Mount Sinai Hospital
Read before the Section on Gastro-Enterology and Proctology at the
Eighty-Fifth Annual Session of the American Medical Association
Cleveland June 13 1934

and chrome inflammation." His symptoms disappeared on ulcer therapy. Four months later there was a recurrence of the dysphagia for a few weeks. He now has ulcer symptoms and radiography reveals an ulcer of the lesser curvature immediately above the incisura angularis.

CASE 5.—M. L., a man aged 55 for four years had attacks of epigastric pain two hours after meals with heartburn and sour belching. He also had mild dysphagia. A fractional test meal showed hyperchlorhydria (64 free acidity). A partial

Fig 1 (case 1)—Irregular narrowing of lower third of esophagus without dilatation above

gastrectomy for multiple duodenal ulcers was performed by Dr A. A. Berg. Following the operation he complained of severe dysphagia, lower substernal pain and sticking of solids at the lower part of the esophagus. Radiography revealed narrowing and irregularity of the lower part of the esophagus (fig 6). The large stomach tube could not be passed beyond 14 inches. Esophagoscopy showed inflammation of the mucosa and the biopsy specimen was reported 'acute and chronic inflammation'. A fractional test meal resulted in a high acid curve (60 free acidity). He was relieved after one month of ulcer therapy. Two months later the same symptoms recurred and roentgenograms revealed marked constriction of the lower third of the esophagus. This time the biopsy specimen was reported 'acute purulent inflammation'. After two months he again lost his symptoms and has remained well for fifteen months.

COMMENT

Certain features are prominent in this group. The patients were all elderly men in whom, because of certain esophageal symptoms, carcinoma was suspected. While the symptoms did suggest the diagnosis of carcinoma, the prolonged course of the disease and the results of biopsy were sufficient to exclude that diagnosis.

It is apparently a chronic disease, characterized by exacerbations and remissions resembling those of peptic ulcer. The association with duodenal ulcer in three cases, and with a preexisting peptic ulcer of the esophagus in case 3, and the subsequent lesser curvature ulcer in another case is striking. The type of substernal pain, heartburn, sour regurgitations and the hyperchlorhydria in all recall the clinical features of peptic ulcer of the esophagus which have been described in

this country by Jackson² and Friedenwald.³ Indeed, the localization is identical and the radiographic observations of an irregular spasm of the lower part of the esophagus without dilatation above are common to the two. However the esophagoscopy in the cases described here reveals a diffuse inflammation without a definite ulcer. The biopsy reports were variously "acute and chronic inflammation" and "acute and chronic purulent inflammation." Ectopic islets of gastric glands were not encountered. Finally the relief obtained by antacid and ulcer therapy is quite definite and impressive. It is easy to exclude other esophageal diseases. Traumas and excessive irritation are conspicuously absent in the history and there was also no suspicion of syphilis. The features here are obviously not those of so-called cardio-spasm, in which the characteristic roentgenogram with a diffuse dilatation with a smooth lower end of the esophagus is always present.

As a result of these observations one cannot avoid the suspicion that the disease in these five cases is possibly a 'peptic' esophagitis, i. e., an esophagitis resulting from the irritant action on the mucosa of free hydrochloric acid and pepsin. The mechanism is not entirely clear. The frequent, almost constant presence of duodenitis and antrum gastritis in peptic ulcer has been well known since the studies of Konjetzny and Puhl in Germany and Aschner in this country. This 'peptic' esophagitis may be analogous to such states. The eroding gastric juice rising into the lower part of the esophagus and held there by a mild spasm of the cardia may injure a mucosa made susceptible by age and the 'ulcer constitution'. Secondary infection

Fig 2 (case 2)—Irregular narrowing and spasm of lower part of esophagus without dilatation

may readily explain the more or less purulent nature of the inflammation. Mild spasms of the cardia and lower esophagus are not uncommonly seen radiographically in peptic ulcer of the stomach and duodenum.

JOUR. A. M. A.
MARCH 16 1935

A review of the literature on diseases of the esophagus has failed as yet to reveal any definite reference to the disease picture herein described. However, the possibility of other agencies should not be overlooked entirely. As emphasized in my paper on cardiospasm,⁴ psychic factors play an important role in the production of esophageal symptoms. It may be that in the cases with actual ulcer the psychic reaction of the individual to his disease induces esophageal or cardiac spasm with a secondary infectious inflammation totally unrelated to an acid or peptic factor. A simple reflex mechanism might possibly do the same.

It is interesting to speculate with these cases in mind, on the symptom of heartburn. This has been explained as due to the action of acid gastric contents on a hyperirritable esophageal mucosa. It seems important, particularly in the severe instances and especially when heartburn is the only symptom of ulcer to examine the lower part of the esophagus by radiography and esophagoscopy for esophagitis. Recently I encountered the following case.

A man aged 55 had suffered for seven and a half years with severe heartburn after meals. Radiographs of the stomach and duodenum was negative. Esophagoscopy by Dr Kramer revealed a swollen mucosa at 34 cm. A biopsy specimen was reported subacute and chronic esophagitis. He had a moderate hyperchlorhydria.

SUMMARY AND CONCLUSIONS

- 1 A group of patients had unusual and distinctive esophageal symptoms.
- 2 The course location, radiologic examination and pathologic features the association with peptic ulcer and hyperchlorhydria, and relief by ulcer therapy suggest that the disease is a "peptic" esophagitis.

Fig 3 (case 2)—Section of biopsy specimen showing epithelial erosion with polynuclear infiltration of the mucosa, submucosa and muscularis.

- 3 Heartburn may be due to "peptic" esophagitis.
- 4 This disease is important in differential diagnosis especially from carcinoma of the esophagus.

1185 Park Avenue

ABSTRACT OF DISCUSSION

DR. CHEVALIER JACKSON, Philadelphia. I am in hearty accord with the writer of this paper. Chronic esophagitis is a common disease due to a variety of causes not all of which are known or at least proved. My experience coincides with that of the author that the cause of this kind of esophagitis is similar to the causes of gastric ulcer but here controversy is

encountered. If we were to start the discussion now on the causes of gastric and duodenal ulcer we wouldn't get through today except with the chairman's help. Nevertheless I think that the word 'peptic' is justified by the fact that all of these ulcers in the esophagus, the stomach and the duodenum are within the area of the gastric juice and for parallel reasons this form of esophagitis, which is also within the area flooded intermittently by the gastric juice I think is quite properly

Fig 4 (case 3)—Irregular spasm of lower part of esophagus.

called 'peptic'. Whether the juice is the primary or perpetuating factor is a matter for discussion. This form of inflammation is often seen at the lower end of the esophagus in cases of herniated stomach, a condition that has become more and more a matter of great diagnostic importance in a patient presenting himself with gastric symptoms. The chief reason I think why so little has been heard of peptic esophagitis is that so few esophagoscopies are done in patients with gastric symptoms. I should like to add a point that I think is borne out by every one of the cases presented by the author, namely, that in every patient with unyielding gastric symptoms esophagoscopy is indicated. It is well known that the roentgen ray is one of the most important of all diagnostic means. But additional information is obtainable with the esophagoscope.

DR. RUDOLPH KRAMER, New York. Dr. Winkelstein has made a contribution to knowledge of diseases of the esophagus in separating this group of cases from the conglomerate mass of heterogeneous conditions involving the lower end of the esophagus. It is an interesting coincidence that two days ago at the American Bronchoscopic Society, Drs. Moersch and Camp reported a series of cases identical with those of Dr. Winkelstein. I think Dr. Winkelstein's hypothesis as to peptic esophagitis and its etiology is most reasonable. There are two conditions both dependent on the time element which appear to be of great importance. In the first one is confronted by a patient in the middle or later years of life with heartburn, dysphagia, substernal pain, loss of weight and irregular constriction of the lower esophagus on roentgen examination and these symptoms have been present for a short period of time. The picture is that of a carcinoma of the esophagus and that is what both the patient and the physician fear is present. In the second situation the patient has had the foregoing symptoms for a long period perhaps several years. Carcinoma although still a possibility is hardly likely to be the cause of the condition. One would consider peptic ulcer of the esophagus or cardiospasm. In either situation recourse must be had to esophagoscopy for a definite diagnosis. The appearances on esophagoscopy are an edematous or a reddened thickened mucosa which may at times be granular. This involves usually the lower half or third of the esophagus but occasionally it may spread upward to involve the rest of it to a lesser degree. In addition there may be an exudate in small patches or in large plaques. There is a marked narrowing

of the lumen which can, however be completely traversed by the esophagoscope and the cardia entered without difficulty. In following out the principle of always doing a biopsy on tissue that has the slightest appearance of abnormality, I have found chronic inflammation of the mucosa and submucosa in all these cases, and acute purulent inflammation often associated with this. There may be variations in the degree of infection in the same case at different periods. This has been noted both on esophagoscopy and on histologic examination of the excised tissues. It is important to rule out carcinoma as soon as possible and further, to institute appropriate therapy as established by Dr Winkelstein so as to prevent the physical and mental deterioration of these patients.

DR. HENRY A. RAFSKY, New York. To detect the lesions of the lower third of the esophagus I wish to call attention to two simple and yet valuable aids. The first is the timing of the swallowing sounds. Normally they should be heard at the cardia from seven to ten seconds after the ingestion of fluids. A persistent delay or absence of the swallowing sounds may be the first indication of the presence of a carcinoma of the lower end of the esophagus. The return of the swallowing sounds is also of prognostic value. An original diagnosis of carcinoma of the esophagus may have to be revised if the sounds return. This was recently demonstrated in a patient at the Lenox Hill Hospital who had a herniated stomach. The string test is also of value in detecting an erosion or a small ulceration of the lower end of the esophagus notwithstanding the fact that other methods fail to reveal the lesion. The presence on the string of two small blood stains, probably no larger than the head of a pin with a clear area of space in between, is pathognomonic of an ulcer or erosion. I recently saw two patients with a syndrome similar to that described by Dr Winkelstein: one was 67 years of age and the other was 70. The patients had in addition periodic manifestations of cerebral arteriosclerosis, and it was interesting—I don't know whether it was a coincidence or not—that when they had a remission in the cerebral symptoms the gastric symptoms likewise cleared up. The pain and heartburn disappeared and the patients

phagia are the outstanding symptoms. The pain of two of our patients reached such intensity that a previous diagnosis of angina pectoris had been made and it was only after electrocardiographic studies and the subsequent course of events that we were able to demonstrate that the pain was definitely related to diffuse spasm of the esophagus. As pointed out by the

Fig. 6 (case 5)—Narrowing and irregularity of lower part of esophagus.

Fig. 5 (case 4)—Irregular narrowing of lower part of esophagus and some irregularity on adjacent lesser curvature.

gained in weight and there was a return of the swallowing sounds. There was a persistent hyperchlorhydria in one patient and persistent achlorhydria in the other.

DR. H. J. MOERSCH, Rochester, Minn. I wish to corroborate the excellent presentation of Dr Winkelstein. As Dr Kramer has stated two days ago before the American Bronchoscopic Society I, in conjunction with Dr Camp of the Mayo Clinic reported a series of cases which, I believe had features identical with those of the group of cases reported by Dr Winkelstein. However, the paper prepared by Camp and me bore the title Diffuse Spasm of the Lower Third of the Esophagus rather than Peptic Esophagitis. Pain and dys-

phagia are the outstanding symptoms. The pain of two of our patients reached such intensity that a previous diagnosis of angina pectoris had been made and it was only after electrocardiographic studies and the subsequent course of events that we were able to demonstrate that the pain was definitely related to diffuse spasm of the esophagus. As pointed out by the

author we believe the condition is associated with intra-abdominal disease. Three of our patients were operated on for intra abdominal disease and with removal of the intra-abdominal condition the esophageal symptoms completely subsided. All our patients were between 50 and 70 years of age and were equally divided as to sex.

DR. ASHER WINKELSTEIN, New York. It is gratifying to hear that a man with Dr Chevalier Jackson's experience in esophagoscopy has seen this type of esophagitis with some frequency. My experience has been limited to eight cases. This is possibly due to the fact that I have studied only cases presenting severe esophageal symptoms. Dr Rudolph Kramer the esophagoscopist at Mount Sinai Hospital, deserves credit for careful and repeated studies of these cases. I still have this group of patients under observation and will carry out Dr Rafsky's suggestions. It is always interesting to hear of the coincidence of scientific observations. The cases mentioned by Dr Moersch are apparently the same as I have described.

Epidemic of the Sweat—The fifth and last epidemic of the sweat occurred in 1551. Again it started in England this time in Shrewsbury, in April, where 900 died in a few days.

Only once after this date (we take our information from Senf) has a sickness resembling the English sweat occurred unless we identify the disease—as many have done—with the Picardy Sweat. About two hundred and fifty years after the fifth epidemic, that is in 1802 at Rottingen in Franconia, a similar but regionally limited malady appeared. It is impossible to identify the sweating sickness with any epidemic disease now prevalent. Purely on the basis of synchronous occurrence, Schnurrer and others believe that it was a modified form of typhus and it is true—as Senf points out—that it did not spread into any of the countries where typhus was prevalent at the time. However, this opinion is not convincing. The sickness remains an entirely individual condition which could not—were it to reappear at present—be properly classified with any of the known infectious diseases—Zinsser, Hans, Rats, Lice and History, Boston, Little, Brown & Co., 1935.

A COMPARISON OF THREE ELECTRICAL METHODS OF PRODUCING ARTIFICIAL HYPERTHERMIA

FRANCIS W BISHOP

EMMY LEHMAN, RN

AND

STAFFORD L WARREN, MD

ROCHESTER, N Y

There has been considerable interest of late in various methods of producing artificial hyperthermia in patients. A comparison of three available "electrical" methods was undertaken in this laboratory in order to study the specific effects, if any, to simplify the procedures used and to reduce the cost of installation and operation of the equipment, if possible. Various workers have reported the use of (a) hot baths,¹ (b) "diathermy currents" (1,000 kilocycles⁻), (c) radiothermy (10,000

Malaria has had a wide usage, mainly because of the apparent simplicity of the clinical procedure. Careful observation of the latter method, however, has demonstrated many of the concurrent physiologic changes common to all methods (blood pressure fall, cardiac or respiratory embarrassment and the like). There are some disadvantageous after-effects of the malarial infection (anemia, intoxication, rupture of the spleen) which are absent when purely electrical methods are used to raise body temperature. The chief disadvantages of the electrical methods for producing fever artificially are the expense of the equipment and the danger of burns (which can be avoided in the main, by suitable technic). In different clinics there is considerable variation in the height to which the body temperature is elevated as well as the duration of the maximum temperature. Some workers elevate the temperature of the patients to a certain point usually from 40.5 to 41 C (104.9 to 105.8 F), after which they allow the

temperature to come down spontaneously, or they delay this fall by the use of hot water bottles or heat pads and blankets. Some imitate the paroxysms of malaria (multiple treatments with short intervals between) while others may give more or less prolonged fever periods with long intervals between them.

Those employing high frequency currents for the production of therapeutic fevers have applied two widely different frequencies—one relatively low around 1,000 kilocycles (300 meters), as generated by the ordinary diathermy machine, the other relatively high 10,000 kilocycles (30 meters) as produced by tube oscillators (radiothermy). Those using the lower frequency apply the current to the patient by means of metallic electrodes held in contact with the body by various jackets or binders. The patient is covered with blankets or encased in an insulating bag and after the fever level is reached the current is shut off and the

temperature allowed to fall spontaneously. Others place the patient in a high frequency field between the two large metal plates of the radiothermy, without actual contact, heating being accomplished by dielectric losses and induced currents. The patient treated by this type of equipment must have the moisture removed from the skin by some means in order to prevent burns if high temperature levels are to be reached.

If we are right in supposing from our clinical results⁴ and laboratory experiments,⁵ that therapeutic fever is effective in certain infections because of the thermal death time, i.e., the time-temperature combination which is necessary to bring about the death of the infective agent,^{6c} it makes but little difference which method of producing the fever is used, provided it can be controlled. It is necessary only to adjust the technic to conform to this principle. Such a concept entails

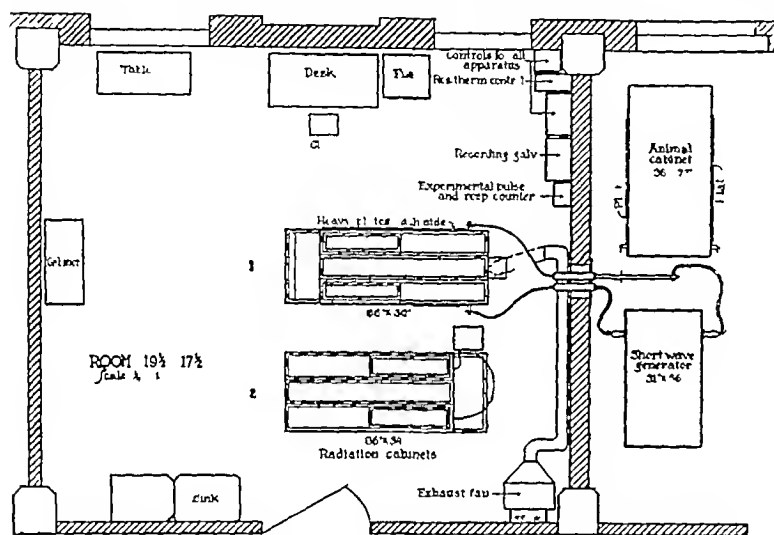

Fig 1—Diagram of treatment room showing arrangement of cabinets, oscillators and control apparatus.

kilocycles³), (d) enclosed bags containing heaters,^{2e} and other methods. Many physicians have utilized chemicals or bacterial products for producing fever

This work was aided by grants from the Rockefeller Foundation for Medical Research.

From the Department of Medicine, Division of Radiology of the University of Rochester School of Medicine and Dentistry.

We are indebted to Dr. W. R. Whitney of the Research Laboratory of the General Electric Company for his cooperation and advice in addition to the loan of much equipment. Dr. C. M. Carpenter gave us many helpful suggestions concerning the experiments with the high frequency oscillator. Dr. McCann, Dr. Morton, Dr. Wilson and others of the clinical staff made available suitable patients for this test. Prof. T. R. Wilkins and B. O'Brien of the Department of Physics gave consultation and advice. Equipment was lent by Mr. Harry Gordon of the Rochester Telephone Corporation, Mr. Henry Klum of the Rochester Gas and Electric Company, Mr. Lamb of the Taylor Instrument Company and Mr. Charles Renaud of the General Electric X-Ray Corporation. Mr. Herbert Mermagen gave technical assistance during the experiments with the high frequency oscillator.

a rather different method of approach to the problem of fever therapy, namely, the elevation of the body temperature to a predetermined temperature and its maintenance there for a specified length of time

The routine in this clinic, in brief, consists in elevating the patient's temperature (rectal) during a period of from one to two hours to a level of from 41.5 to 41.7 C (106.7 to 107 F) and maintaining it there for five hours or longer, since it was found that this time-temperature relationship was generally efficacious, although any other procedure or time-temperature relation may be used if found to be therapeutically

Fig 2—Radiant energy cabinet open showing the simple arrangement of lamps with screens which prevent contact with the patient

effective. At the end of the interval the temperature of the patient is lowered by blowing cool air on the skin with a fan.

Temperature, pulse, respiration, blood pressure, heart sounds, color changes and the like are watched carefully throughout the procedure. The clinical procedure is essentially the same regardless of the method of producing the fever and has been described in greater detail in a previous paper¹¹ in which the diathermy equipment was used.

The average ambulatory patient is rather tired following the treatment but is usually well enough to

Fig 4—Dimensional and constructional details of radiant energy cabinet.

be discharged from the hospital the next day. The procedure is safe for the patient who is in fairly good general physical condition. Many different diseases have been studied and treated and while the physiologic changes obtained both during and after the fever have been essentially identical with all three described methods, they are not within the scope of this report. The methods and apparatus used are now well organized, as far as general principles are concerned, and may be readily adapted to fit special conditions.

INSTALLATION OF APPARATUS

In order to evaluate the various electrical methods of elevating the temperature of a patient, the treatment room was equipped to meet all requirements. In one corner of the treatment room (fig 1) is a wall-mounted control box, with a number of outlets controlled by various switches. All apparatus is controlled from this point. The box contains all necessary rheostats and meters. Above this control panel is a shelf which holds a duplex recording galvanometer and accessory apparatus for the resistance thermometer, a recording wattmeter, a watt-hour meter and other equipment.

Fig 3—Box closed. Lamp housing hinged back provides accessibility.

The first type of apparatus used for the heating of the patient is an ordinary high power "diathermy machine" with a frequency of 1,000 kilocycles (300 meters) and an available current through the patient of from 5 to 6 amperes. This is applied to the trunk of the patient by means of large block tin electrodes. As pointed out in a previous publication,¹¹ the method entails not only the efficient elevation of the patient's temperature but also its maintenance over a considerable period of time (five hours or more). Means must be provided to prevent the loss of heat by the patient during the rise and to compensate for the losses during the period of maintenance of his fever. Blankets (from eight to fourteen) and hot water bottles have been

employed, but their use was soon discontinued because the blankets are heavy and cause a sense of restraint. They were also difficult to manipulate during the treatment for blood pressure, examinations, making of electrocardiograms, use of urinals, and change in position. Moreover, the laundry cost is high for the blankets, so that we use a heat-retaining chamber or cabinet by preference.

This "cabinet" consists of a shallow wooden box which rests on the framework of the common hospital

cot and contains a rubber-covered mattress measuring 80 by 200 cm (31 by 79 inches). Hinged to this box is a light, somewhat coffin-shaped box made of cellophane fastened to a wooden framework which when closed,

Fig 5—Comparison of normal curves obtained by the three methods of elevating body temperature. Upper diathermy, center radiothermy, lower radiant energy.

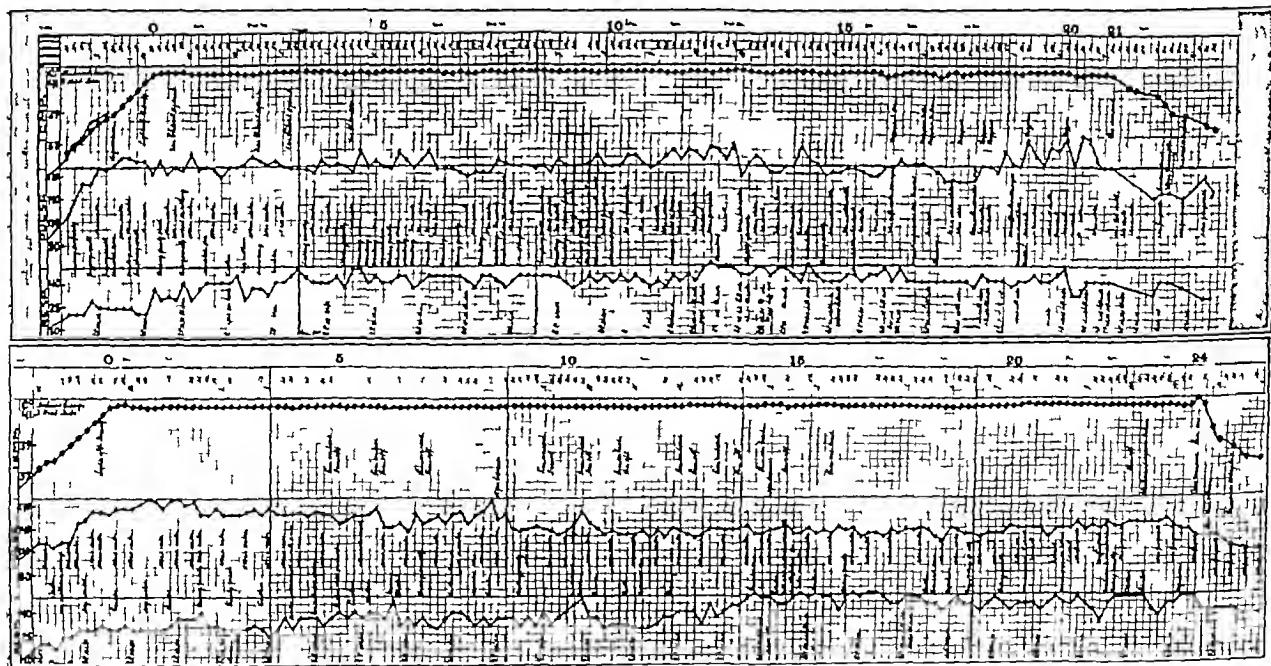

Fig 6—Two characteristic curves of temperature, pulse and respiration in patients maintained for twenty-one and twenty-four hours respectively at 41.5°C (106.7°F) rectal temperature by the radiant energy method.

fits tightly around the mattress.^{2a} The exterior has been gayly painted to lessen the sepulchral appearance. For use with the diathermy or low frequency equipment, the box was wired for eight 60-watt carbon filament lamps controlled by a rheostat. By this means the air surrounding the patient may be maintained at a temperature sufficiently high to compensate for losses of heat

from the patient by radiation, sweating and the like. The head of the patient protrudes from one end of the box through a large opening provided for this purpose. Two pieces of terry cloth, cut to conform to the shape of the neck are hung, one inside and one outside, of the box. Regardless of how the patient moves about, at least one of these is effective in closing the space around the neck. Fixtures for attaching restraining cuffs for the hands and ankles and the axillae are available. Two doors are provided on each of the sloping sides of the box to permit examination or manipulation of the patient during the treatment. Small windows allow observation of respiration and reading of any instruments within. Small holes are provided to permit the use of thermometers for observation of the air temperature as well as for a recording rectal resistance thermometer kept constantly in the patient, and for electrocardiographic leads and the like. When the patient's temperature is at the desired height, the electrodes for the high frequency (diathermy) currents may be removed and the temperature maintained by the lamps.

The second method (radiothermy) employs a system of two 500-watt radio transmitting tubes, oscillating in a push-pull Hartley circuit at a frequency of approximately 10,000 kilocycles, or a wavelength of 30 meters. This circuit and the generator have been described by Page⁶ and are similar to those used by Bierman,^{2b} Hinzie and Carpenter,^{3c} Neyman,^{2e} Simpson,^{2f} Tenney^{3g} and others. With such high frequencies it is merely necessary to place the patient in some available part of the field of the oscillatory circuit, whereupon currents are set up in the body resulting in the genera-

tion of heat. The common method has been to place the patient on a stretcher on the oscillator housing, in the electrostatic field between the large protected plates supplied by the manufacturer as standard equipment. If the temperature of the patient is to be elevated to

41.5 C (106.7 F) and kept at this level, it is essential for the patient to be under constant observation during the procedure. Since this temperature is near the upper limit of safety, it is necessary to make frequent temperature observations (every ten minutes). From the clinical standpoint the position of the patient is very unsatisfactory in such an arrangement, so that we have changed the setup somewhat by using a cabinet separated from the oscillator.

On account of limited space in the treatment room, the "short wave" (30 meter) oscillator is placed in an adjoining room (fig 1) and is operated by remote control from the panel in the treatment room. The radio frequency conductors are brought through the 22 cm (8½ inch) brick wall in porcelain tubular insulators. The leads through the wall are separated by a distance of only 8 cm (3¼ inches), constituting, in effect, a radio frequency feeder system. Separation of the leads through the wall to any great extent results in large losses from absorption by the bricks. The conductors entering the treatment room terminate in sockets into which the leads from the patient's treatment cabinet are plugged. The length of each lead from the wall socket to the plate in the cabinet is 120 cm, through the wall 22 cm, and from the wall leads to the machine 100 cm, or 242 cm total per lead.

The cabinet for use with the short wave (30-meter) machine is similar in shape to the one described.^{2a} Several other arrangements may work satisfactorily, but we have found the use of a cabinet to be simple and convenient. This cabinet is also of cellotex and is shellacked to prevent absorption of moisture. It is mounted on a wooden frame on casters instead of a metal cot, because of the absorption of power by the latter material in a rapidly fluctuating field. The box and its surroundings should contain a minimum of metallic objects or other conductors (including paint). A mattress would accumulate moisture during the treatment, so that a canvas stretcher is provided, which has openings along the edges for the circulation of air. The space below the stretcher is enclosed and forms a duct through which warm or hot air may be forced. Within each of the double-walled sides of the cabinet is an aluminum plate, 25 cm by 130 cm by 1.5 mm thick, which may be slid lengthwise for optimum orientation of the field in relation to the patient. These plates are 74 cm (29 inches) apart and are connected to the high voltage terminals of the transmitting helix, thus forming part of the oscillatory circuit. It is, of course, as necessary as before to minimize heat losses. While heating lamps cannot be placed within the cabinet, it is still possible to warm it by other means and incidentally lessen the accumulation of moisture on the patient, which, because of its conductive properties, would allow currents to concentrate on the skin of the patient and produce burns. At the end of the air duct, beneath the stretcher and sufficiently far removed from the plates, are several resistance type heaters connected to the control panel on the wall by a cable. At the opposite end of the cabinet, and attached so as to remove the air from above the stretcher, is a 145 cm (60 inch) length of 10 cm (4 inch) semirigid rubber and canvas hose connected to an exhaust fan. Hot air is thereby drawn along and under and over the patient constantly drying up perspiration, and the hot, humid air is removed from the cabinet and room. The cabinet may be lifted back on its hinges without interfering with the hose

connection. The top of the cabinet has a removable panel, which can be replaced by a cellotex panel on which are mounted in a row six 60 watt carbon filament bulbs in standard parabolic reflectors. These lamps are put in place after the temperature of the patient has reached the desired level and the high frequency machine has been shut off, because the wires and reflectors shunt a large amount of energy from the patient. These lights can be controlled by their individual socket switches or by a rheostat and are sufficient to maintain the patient's temperature while he is in the cabinet. Windows and doors are provided, as in the first cabinet. A resistance thermometer or thermocouple cannot be used with this high frequency apparatus while the high frequency current is on. It is necessary to shut off the machine to take the rectal temperature, even with a standard mercury thermometer, or to listen to the heart or to take the blood pressure. When the patient's temperature has reached the desired level it can be maintained by using the radiation from the lamps in the removable panel, and any thermometer can be used. The moving hot air alone is insufficient to maintain the temperature level because of the heat loss due to the evaporation of sweat, unless high air temperatures (60 C [140 F] or more) are used. It is not desirable to continue the use of the high frequency currents during the long period of maintenance because of the danger of burns, although this technic is possible with suitable precautions.

A number of experiments were conducted to determine whether or not the alternating electromagnetic field from a solenoid energized by the high frequency currents had any particular properties that would give it an advantage over the ordinary high frequency electrostatic field. It was hoped that the currents induced in the body by this means might be of sufficiently low potential to permit the use of electrical thermometers and possibly reduce the danger of burns on the skin. Helices of sizes up to those permitting the insertion of the entire body were employed. While very high powers were not available, it was found that the electromagnetic field per se possessed no particular advantage over the electrostatic field as far as its applications to systemic fevers were concerned, although it seemed to have possibilities for local administrations. A fairly wide frequency range or spectrum was investigated. (The radiotherm was built and lent to us by the General Electric Company through the courtesy of Dr W R Whitney.)

A third method (radiant energy), which now supercedes the others in our clinic, is the result of our observations that the use of the lights in the treatment box had a considerable accelerating effect on the rise in the patient's temperature. It was soon found that, with suitable changes in the cabinet, the temperature of the patient could be elevated by the use of the lamps in the box alone (radiant energy) without the use of any high frequency currents. This principle is old but is one that has not been much adapted to meet present requirements. It was suggested that the absorption of the infra-red radiation by the skin was largely responsible for the rise in the patient's temperature. Experiments were conducted to test this point. With other conditions remaining the same, the same bulbs in the box were painted black to reduce the shorter wavelength radiation but still allowing the air to be heated as before (from 50 to 60 C [122 to 140 F] during

elevation of temperature, and from 30 to 45 C [86 to 113 F] during maintenance) It was found that under these conditions the patient's temperature rose very slowly Substituting clear bulbs of the same wattage for the painted ones caused a marked increase in the rate of rise of the patient's temperature without a significant change in the temperature of the air surrounding the patient It was then decided to place more powerful bulbs in reflectors, mount them on the exterior of the box, and irradiate the patient through holes cut in the flat roof of the cabinet (figs 2, 3 and 4) Five 200 watt Robert Schwartz heating lamps are so arranged that three irradiate the trunk of the patient and two the lower extremities Two smaller bulbs are mounted in the foot end of the box This type of lamp was chosen because they are strong emitters of infra-red rays Tungsten lamps of the same wattage were not so satisfactory These lamps are controlled by a rheostat since they deliver more energy than is usually required The life of the bulbs is prolonged, since they are operated at less than their rated voltage These changes were made in the first cabinet described so that it can now be used either with the diathermy machine or with radiant energy alone

COMPARISON OF METHODS

Since January 1930, 448 treatments have been given to 312 patients The diathermy method was used for 157 treatments, the radiotherm for twelve treatments, on twelve patients and the radiant energy method for 279 treatments Three of these patients were treated with both the radiotherm and diathermy, with an interval of from one to three weeks between

Since the results in this clinic seem to be identical, no matter what the method of elevating the temperature may be (fig 5), a comparison may be based on cost and ease of use

The first method requires a diathermy machine of fairly large power, representing an investment of from \$200 to \$900, with associated equipment such as electrodes and binders There will be a certain cost of maintenance Considerable time is required to apply the electrodes properly, as well as to readjust them if they become disarranged during the period of heating If the electrodes become loosened through movements of the patient, electrical burns are likely to occur In unstable or refractory (paretic) patients this is a potential danger There may be variable upward coasting of the patient's temperature after the diathermy machine has been turned off (fig 5), depending on the amount of heat temporarily stored in the tissues through which the current has been passing The energy applied by this method is rather localized, and the rise in general temperature is brought about by the circulation of the heated blood to other parts of the body

There is usually some fall in the patient's temperature when the box is opened to remove the electrodes This has to be made up subsequently With this method a higher pulse rate is noted (fig 5) (10 per cent average above patients heated by infra-red radiation only), and it is believed to be due to a greater heating of the heart and lungs by the passage of the current through them, or due to the patient's apprehension from restraint of the chest (electrode binder)

Considering the method that employs the short wave oscillator, radiotherm, we find that the initial investment

is very high This equipment has the advantage over the directly applied electrode method in that the patient is not so restrained The small number of actual treatments utilizing the radiotherm represents six months' active experimentation with this procedure The effect of varying the electrode size and distance, their position in relation to the body, and major changes in wavelength were studied Efficient methods of passing hot air over the patient and eliminating excessive cooling by the rapid evaporation of the sweat had to be worked out All this was expensive and time consuming After the greatest simplification was achieved (fig 1), the equipment was still cumbersome and difficult to manage from the nursing standpoint in contrast to the other methods The equipment was satisfactory for lower ranges of fever temperature, and several lower powered oscillators have been constructed in this laboratory and used with very satisfactory results for local applications⁷ The safety of the patient at the high level of 41.5 C (106.7 F, figs 5 and 6), where sudden elevation to dangerous temperatures (42 C [107.6 F] or above) may occur, demands frequent temperature observations This is difficult to do with the current on, and the high frequency currents must be shut off for the rectal temperature to be taken The mouth and axillary temperatures are unreliable We feel, however, from our rather extensive experimentation with this equipment in patients, on ourselves and in animals, that the clinical results obtained are based, in the main, on the heat produced in the body of the patient and are no different from those obtained by any other electrical method of elevating the temperature While little is actually known about the temperature gradients occurring in patients treated by the radiotherm, we believe that, if any selective heating of an organ is brought about by a difference in its electrical characteristics, the effects are neutralized by the blood flow Aside from this, it would seem a difficult matter to utilize any specific heating effects, even if they can be demonstrated on excised tissue,⁸ since the intensity and orientation of the field (and consequently the heating) varies so much from patient to patient and to a great degree in the same individual if his position in respect to the plates is changed

In the third system under consideration radiant energy (infra-red and visible radiation) is applied to the skin over a large area The distribution of heat is brought about in the same manner as all other methods, i. e., the circulation of the warmed blood to other parts of the body The heat transfer of the method is comparatively rapid, since the blood is so diffusely distributed over the whole body in the capillary bed of the skin that it is readily heated by the absorption of the radiant energy The temperature rise starts immediately after the patient is exposed to the radiation and the rise is uniform and ceases practically at once when the radiation is turned off The fact that there is little or no upward coasting of the patient's temperature when the radiation is turned off indicates that the blood stream conveys the heat away about as fast as it is supplied, and therefore the skin temperature is not excessively raised (maximum 43 C before sweating begins) Blisters may be produced if the energy input is pushed too far in some area of decreased cir-

culation (scars, edematous areas and the like), or if some part should come too close to the lamps. These can be avoided if a towel or sheet is placed over the part as soon as a hyperemia is noted. Any method that applies energy diffusely over a large area of the body automatically reduces the danger of too great concentration and consequently burns. It seems obvious from a physical standpoint, physiologic processes (sweating) being disregarded, that to raise the temperature of a patient of a certain weight to a given degree it will require the absorption and retention of a definite amount of energy. For example, assuming 0.83 as the average specific heat of tissue and $h = 0.24 I^2 R t$ (Joules law), to raise a 60 Kg patient 5 degrees C in one and a half hours would require an effective energy of approximately 200 watts continuously applied during the interval, or 300 watt hours.

The energy put into our cabinet (from 0 to 1,000 watts) is ample to overcome all such losses as the evaporation of sweat, the heating of the box and enclosed air, and heat losses from all other causes, with sufficient reserve to supply the 200 watts or more necessary to raise the patient's temperature the required number of degrees in the specified time. Two or three ordinary electrical heating pads embedded in the mattress are sometimes used to prevent a possible heat loss in this direction. In practice their influence is slight, since the box and mattress are preheated by the lights and the mattress is a rather poor heat conductor. Humidity control of the air in the radiant energy cabinet was investigated and was found to be of little benefit in the set-up described, especially in view of the complications that it imposed.

The use of radiant energy has also made it possible to extend the period of fever greatly at any given height (from twenty-one to twenty-four hours) (fig 6). Any rise or fall in rectal temperature may be compensated for very simply and quickly by use of the rheostat. The simplicity of the equipment enables one to administer to the comfort of the patient somewhat, such as by changes in position, pillows and rubber rings, and to foresee and handle sudden changes in condition. It is possible to direct a small electric fan at the patient's head and let him have cracked ice at intervals, since the heat loss from this cause can be made up easily. The cost (\$150) entails the building of a suitable cabinet wired for the lamps and the purchase of a rheostat. The usual thermometers, blood pressure equipment, oxygen tank and records complete the equipment. A standard indicating or registering resistance thermometer may be purchased for from \$150 to \$300 from several instrument makers. A constant indication of the rectal temperature aids greatly in manipulating the heat input to maintain the rectal temperature at a desired level (fig 6).

SUMMARY

1 While any of the electrical methods proposed can be made to work efficiently and safely in artificial hyperthermia, the radiant energy (infra-red) method described seems to be the most convenient and economical method in our experience.

2 There does not appear to be any difference in the clinical effects and results from the various methods used.

3 All these methods rely on the circulation of the blood for the redistribution of heat in the body from the site of application of the energy.

Clinical Notes, Suggestions and New Instruments

CASE OF DINITROPHENOL POISONING WITH RECOVERY

J C GEIGER M D SAN FRANCISCO
Director of the Department of Public Health

B L., a girl, aged 18 years, admitted to the Central Emergency Hospital, Department of Public Health, Dec 6, 1934, at 6 30 p m, had taken twenty-four reducing capsules with suicidal intent.

On physical examination the patient's face was flushed, the respiration rate was rapid and short, from 38 to 40 per minute, the pulse was 144, and the temperature was 103.4 F.

Routine gastric lavage was done with a 5 per cent solution of sodium bicarbonate. The symptoms being those associated with an overdose of alpha-dinitrophenol, the patient was placed in an ice pack in order to bring down the temperature. This was repeated whenever the temperature went over 101 F. Oxygen was administered at intervals that evening, and 500 cc of dextrose was administered intravenously.

The patient slept at intervals the first night, and the next night she complained of being hungry but vomited after taking some food. The patient's condition was much improved the second day. She took fluids freely retained them, and felt very much better. Recovery continued uneventfully and the patient was discharged at 4 p m, December 8.

The patient, in describing symptoms afterward, stated that during the entire time she felt as if she were on fire.

At no time was consciousness lost, and there was little or no pain evident during the stay in the hospital.

Dinitrophenol was found in the gastric contents on laboratory examination.

Civic Center

A CLINICAL STUDY OF BILIARY SECRETION IN A CASE PRESENTING A COMPLETELY OBSTRUCTED COMMON DUCT

LAWRENCE B. SHELDON M.D. DALLAS, TEXAS

This case is of interest because it enabled me to study accurately the biliary secretion for a period of three months.

REPORT OF CASE

A white woman aged 65, had had a cholecystectomy five years before, at which the gallbladder with several hundred small stones was removed. Following the operation she was symptom free for about three and one-half years. Then for the next eighteen months she suffered from intermittent attacks of severe pains in the upper part of the abdomen. A marked jaundice and septic-like temperature as high as 104 F was associated with these attacks. It was at this stage that the patient came under observation. A diagnosis of common duct obstruction was made. The patient was prepared for surgical intervention by the administration of calcium salts, intravenous dextrose and hypodermoclysis of saline solution. At operation a markedly dilated common duct was found with complete obstruction at the point of entrance into the duodenum. The surgeon was unable to pass a probe through the stricture. A T tube was inserted into the common duct and large amounts of purulent bile were drained freely. Following the operation the patient improved rapidly and each day the bile became less purulent. The T tube was left in for a period of three months, and it was during this interval that the clinical studies were made.

The following conditions were present which made this an unusual case for the study of biliary secretion.

1 The gallbladder had been removed five years previously. The hepatic ducts had had sufficient time to dilate and if possible to assume partially the functions of the gallbladder. The hepatic ducts were demonstrated to be dilated by an x-ray study in which skiodan had been injected into the common duct by the T tube. (It was interesting to note the precordial type of pain, anginoid in character, that was experienced by

the patient when too great pressure was used in filling the duct.)

2 A complete occlusion of the common duct had occurred just proximal to its opening into the duodenum. Thus, none of the bile secreted by the liver could pass into the duodenum. This complete obstruction was demonstrated at the time of operation by the x-ray study with opaque mediums injected into the ducts and by clinical observation over a period of three months. During this time the stools were always colorless and several chemical tests for bile were negative.

3 The T tube inserted into the common duct made it possible to collect and measure all the bile secreted by the liver, thus overcoming the inaccuracy of collecting bile specimens through the duodenal tube. I was aware of the fact that this liver was not a normal one and that impaired function

Because of general discomfort abdominal pains and cramping I was unable to carry the study for a longer period.

6 Tincture of belladonna was administered to the patient until tolerance was determined, and then the twenty-four volume was measured, giving the following results 615, 604, 691, 633 and 608, an average of 626 cc. This compared favorably with the average volume during the control period.

7 Sodium salicylate, 38 grams (2.5 Gm.) daily, resulted in 570, 585, 542, 570, 683 and 541, an average of 598 cc. of bile.

CONCLUSION

From the studies made in this case there is no evidence that the dilated hepatic ducts had assumed any of the functions of the gallbladder. The rate of bile flow was almost constant, whether measured hourly or daily. No appreciable change was noted following meals, nor was increased flow noted after the administration of bile salts plain, bile salts compound, sodium salicylate or tincture of belladonna.

1606 Medical Arts Building

TABLE 1—Hourly Variations and Relationship to Meals

Breakfast	8 a m		
	9	45 cc	45 cc
	10	30 cc	30 cc
	11	30 cc	38 cc
	12 m	45 cc	30 cc
	1 p m	15 cc	33 cc
Dinner	1:30 p m		
	2	38 cc	70 cc
	3	30 cc	45 cc
	4	20 cc	45 cc
	5	38 cc	24 cc
	6	30 cc	45 cc
Supper	7 p m	34 cc	30 cc
	8	30 cc	30 cc

with a hepatitis was present, the result of a long standing infection within the biliary system. If cholagogues have a place in therapy, such a condition should be one of the indications for use.

STUDIES

1 The hourly variations and relationship to meals are given in table 1. A general diet was given with no restrictions of ordinary fats such as butter and cream. Fried and greasy foods were avoided. There seemed to be little change in the rate of flow when measured hour by hour. Foods ingested caused no appreciable variation.

2 A comparison of the day and night volume of bile is given in table 2. The volume was slightly larger during the night period between 8 p m and 8 a m, the amount not being great enough to be of any significance. There seemed to be a little

TABLE 2—Comparison of Day and Night Volume of Bile

	Day				Night			
	8 A	M	3 P	M	8 P	M	8 A	M
Monday	315				255			
Tuesday	300				345			
Wednesday	270				300			
Thursday	355	Average 293				255	Average 320	
Friday	300				360			
Saturday	255				700			
Sunday	257				315			

relationship in the total twenty-four volume in that a lower day output seemed to be offset by a greater night and a greater day volume by a lower night volume.

3 The daily twenty-four hour volume variations with the patient ambulatory and on a general diet were 632, 871, 665, 677, 721, 690, 542, 633, 521 and 608, an average of 656 cc. The average bile flow during this trial period of ten days with no medication was a little higher than the average daily flow of the whole experimental period which was 624 cc. daily.

4 Stimulation with bile salts plain 30 grains (2 Gm.) daily, resulted in the following volumes 592, 577, 682, 617, 675, 652 and 622, an average of 631 cc. No appreciable change was noted during this period.

5 Stimulation with a compound consisting of bile salts 2½ grains (0.16 Gm.) cascara extract one-half grain (0.03 Gm.), and phenolphthalein one-half grain given three times a day, resulted in daily volumes of 660 and 602, an average of 631 cc.

GLANDULAR PHYSIOLOGY AND THERAPY

DIABETOGENIC, THYROTROPIC, ADRENOTROPIC AND PARATHYROTROPIC FACTORS OF THE PITUITARY

J. B. COLLIP, M.D.

MONTREAL

(Concluded from page 857)

NOTE.—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues of THE JOURNAL. When completed, this series will be published in book form—Ed.

THE PANCREATROPIC HORMONE OF THE PITUITARY

Although Koster⁹² states that the pancreas of hypophysectomized dogs is usually atrophic, no specific changes have been observed in the islands of Langerhans that would prove a regulatory influence of the hypophysis on the endocrine activities of the pancreas.

Anselmino and Hoffmann⁹³ have recently stated that administration of anterior pituitary extracts increases the size and number of the islands of Langerhans in the pancreas of the rat. They believe that this effect is due to a specific pituitary hormone, for which the name "pankreatrope Substanz" (pancreatropic substance) has been suggested. Further experiments by the same authors⁹⁴ indicate that this principle leads to a (very slight) decrease in the blood sugar of dogs and rabbits. In the rat the liver glycogen disappears almost completely after an amount of pancreatic substance equivalent to 10 mg. of anterior lobe tissue. The authors conclude that this hormone stimulates the insulin production of the islands of Langerhans.

93 (a) Anselmino K. J., Herold L. and Hoffmann F. Ueber die pankreatrope Wirkung von Hypophysenvorderlappensextrakten. Klin. Wchnschr. 12: 1245-1247 (Aug. 12) 1933. (b) Anselmino K. J. and Hoffmann F. Die pankreatrope Substanz aus dem Hypophysenvorderlappen: über die Darstellung und die Eigenschaften der pankreatropen Substanz. ibid. 12: 1435-1436 (Sept. 16) 1933.

94 Hoffmann F. and Anselmino K. J. Die pankreatrope Substanz aus dem Hypophysenvorderlappen: über die Stoffwechselwirkung der pankreatropen Substanz. Klin. Wchnschr. 12: 1436-1438 (Sept. 16) 1933.

It is interesting in this connection that Aron⁹⁵ found that in guinea-pigs the intra-uterine injections of thyrotropic hormone during pregnancy will increase the number of the islands of Langerhans in the fetal pancreas. According to Anselmino and Hoffmann,^{95b} however, it is not likely that their own results were due to the thyrotropic hormone, since their extracts were free of the latter.

NATURE OF THE DIABETOGENIC PRINCIPLE

Practically all workers in this field have noted that anterior pituitary extracts purified to a greater or less degree, which have a diabetogenic effect on Houssay dogs, also produce an acetonuria in fasted normal or in fat-fed normal animals. The question arises, therefore, as to whether the ketogenic principle of the pituitary is the diabetogenic substance. We have had considerable experience in our laboratory in the fractionation of anterior pituitary extracts, and our own results have shown that the diabetogenic effect is retained by our purified growth hormone extracts and that our best thyrotropic hormone extracts contain varying amounts of ketogenic activity. We feel that our experiments on the ketogenic effects of anterior lobe extracts have established quite conclusively that the ketogenic effect is due to a substance separate and distinct from the thyrotropic principle. The fact that a purified extract rich in the thyrotropic and ketogenic principles, but free of growth principle, failed to cause an increase in the blood sugar or the excretion of sugar in the urine of a Houssay dog, whereas a purified growth extract containing only traces of the latter principles caused a marked increase in the fasting blood sugar level and in glycosuria, is, we think, absolute proof that the substance acting on blood sugar is different from the ketogenic hormone. Also this growth extract has been shown to antagonize insulin in the normal rabbit, whereas no such effect was obtained with the thyrotropic ketogenic extract.

We may conclude that the diabetogenic effect of the anterior pituitary is due to the combined action of two substances, one acting on the blood sugar level and the other producing ketosis.

The work of our laboratory on antihormones has helped greatly in the solution of the problem of the nature of the diabetogenic action of the pituitary. We have shown that the ketogenic substance must be distinct from the thyrotropic principle.⁹⁶ Animals injected over long periods with ketogenic extracts have become resistant to it, and the serum of these resistant animals has been shown to antagonize the effect of ketogenic extracts in other animals. Such serums have also antagonized the thyrotropic hormone but this has been due to the presence of both principles in the extracts used to produce the resistant state.

Recently we treated a pancreatectomized dog with an anterior pituitary extract rich in both the growth and the ketogenic principle for a period of four months. Insulin was then withdrawn. For a period of one month thereafter the animal showed no increase in acetonuria. Marked hyperglycemia and glycosuria were present. The animal was in good health and in fact resembled the typical Houssay animal. The animal was

killed thirty-seven days after the withdrawal of insulin and the completeness of the pancreatectomy established. The liver glycogen was 1.8 per cent.

II THE THYROTROPIC PRINCIPLE

The interrelationship between the pituitary and the thyroid, which recent work has established so definitely, was suggested first by Rogowitsch,⁹⁷ who noted enlargement of the pituitary of dogs and rabbits following thyroidectomy. Rogowitsch's observation has been confirmed repeatedly. A significant increase in the size of the pituitary has been observed in cases of cretinism, myxedema and cachexia thyreopriva (Boyce and Beadles,⁹⁸ MacCallum and Fabian,⁹⁹ Wegelin¹⁰⁰). Adler¹⁰¹ discovered that cauterization of the hypophyseal anlage in larval amphibia prolonged the larval state. Coincident with this, Gudernatsch¹⁰² found that precocious metamorphosis was induced in tadpoles by thyroid feeding. Allen,¹⁰³ using the Adler technique for removal of the pituitary, showed that the delayed metamorphosis of hypophysectomized tadpoles was associated with scanty deposition of colloid in the thyroid. The Snuths¹⁰⁴ reported that the thyroid of hypophysectomized tadpoles became extremely atrophic and that repair of the thyroid could be brought about by homotransplants of pituitary or by intraperitoneal injections of extracts of bovine anterior pituitary. Spaul¹⁰⁵ produced hypertrophy of the thyroid and acceleration of metamorphosis by injections of anterior pituitary substance. Uhlenhuth and Schwartzbach¹⁰⁶ showed that salamander larvae injected with anterior pituitary extracts consumed 40 per cent more oxygen than normal larvae. The classic work of P. E. Smith¹⁰⁷ on hypophysectomy of the rat established quite conclusively that the thyroid is dependent on the stimulating action of the pituitary, associated with the atrophy of the thyroid of the hypophysectomized rat. Foster and Smith¹⁰⁸ found that the metabolic rate was decreased as much as 35 per cent.

A close relationship between the pituitary and the thyroid has been demonstrated clinically. Cushing¹⁰⁹

stated that patients with hypopituitary conditions tend to have a subnormal metabolism Graubner,¹¹⁰ reviewing the reports of thirty-three cases of pituitary cachexia (Simmonds' disease) found that in each instance the thyroid was small and atrophic and frequently sclerotic

Loeb¹¹¹ and Aron,¹¹² quite independently of each other, produced hyperplasia of the thyroid of the guinea-pig by means of anterior pituitary extracts Numerous workers have reported since on the production of hyperplasia of the thyroid in a variety of laboratory animals Janssen and Loeser,¹¹³ Watrin and Florentin,¹¹⁴ Grab,¹¹⁵ and Junkmann and Schoeller,¹¹⁶ in the guinea-pig, Benedict, Putnam and Teel,¹¹⁷ Houssay, Biasotti and Magdalena,¹¹⁸ and Schittenhelm and Eisler¹¹⁹ in the dog, Baumann and Marine⁷ in the rabbit, Riddle and Polhemus¹²⁰ in the pigeon, Noether¹²¹ in the hen, Schockaert¹²² in the duck, Anderson and Collip¹²³ in the rat

Hyperplasia of the thyroid of the guinea-pig has been demonstrated in vitro with the thyrotropic hormone by Eitel, Krebs and Loeser,¹²⁴ while Houssay, Biasotti and Magdalena¹¹⁸ and Marine and Rosen¹²⁵ produced hyperplasia in homotransplants and autotransplants of thyroid tissue in animals injected with anterior lobe extracts

It has been stated by some that thyrotropic hormone is present in urine (Aron and Klein¹²⁶), while others have failed to substantiate this (Smith and Moore,¹²⁷ del Castillo and Magdalena,¹²⁸ Krogh and Okkels¹²⁹)

The thyrotropic principle is not active by mouth and it is destroyed by boiling Active extracts have been prepared in a variety of ways (Loeser,¹³⁰ Junkmann and Schoeller,¹¹⁶ Anderson and Collip¹³¹)

It can be shown to be distinct from the maturity factor, which is usually present in greater or less amount in active extracts and by the fact that boiling destroys the physiologic action of the former but not of the latter principle

It is different from the growth hormone, because the most sensitive test object, the recently hypophysectomized rat, fails to grow when injected even for long periods with the purified thyrotropic hormone extracts

According to Loeser¹³² the thyrotropic hormone leads to an increase in size of the adrenal cortex, but only in the presence of the thyroid

THE PHYSIOLOGY OF THE THYROTROPIC HORMONE

The administration of adequate amounts of the thyrotropic hormone to normal animals results in the course of a few days in enlargement and hyperplasia of the thyroid There is an increase in the metabolic rate (Siebert and Smith,¹³³ Verzar and Wahl¹³⁴), increase in heart rate (Schittenhelm and Eisler¹³⁵), exophthalmos (Schockaert,¹²² Loeb and Friedman¹³⁶), a reduction of the iodine content of the gland (Loeser,¹³⁰ Schockaert and Foster¹³⁷), an increase in the alcohol-insoluble iodine of the blood (Closs Loeb and MacKay¹³⁸ Grab,¹³⁹ Schittenhelm and Eisler¹³⁵), a depletion of liver glycogen and an increase in the acetone bodies in the blood (Eitel and Loeser,¹⁴⁰ Eitel, Löhr and Loeser¹⁴¹) The latter effect, as has already been shown, is due to the ketogenic and not to the thyrotropic principle Verzar and Wahl¹³⁴ and others have shown that none of the signs of hyperthyroidism can be produced in thyroidectomized animals by injections of thyrotropic hormone extracts

The average increase in metabolic rate that we have seen in normal rats of our colony, treated with the thyrotropic hormone, has been +26 per cent The administration of even massive doses of the hormone

does not result in higher values. We obtained quite different results, however, with a small series of gonitrous rats. A control animal in this group had a thyroid gland weighing 142 mg as compared with a normal rat's gland of 20 mg. The gland proved, on microscopic examination, to be extremely hyperplastic. The control metabolic rates of these animals were slightly subnormal. Immediately following treatment with thyrotropic hormone the metabolic rate rose rapidly. One animal showed a 95 per cent increase within twenty-four hours. The highest rate observed in the group was 162 per cent of the normal. This was on the ninth day of injections. All the rats showed definite symptoms of hyperthyroidism, irritability, weakness, exophthalmos and excessive sweating, and there was a 20 per cent loss of weight in the course of nine days.

Our hypophysectomized rats show a decline in the metabolic rate to an average of 74 per cent of normal as determined on a series of 118 of our experimental animals. The thyroid gland decreases in weight and the microscopic picture is one of marked involution of the cellular elements. We have found that these animals are much more sensitive to injections of the thyrotropic hormone than are normal animals. They compare very favorably in this respect with the guinea-pig. The metabolic rate has frequently been restored to normal within a week with doses twice a day of as little as 0.005 cc of a purified thyrotropic extract. (The normal rat has required at least 0.08 cc twice a day to show a significant rise in metabolic rate.) We have chosen as an arbitrary unit of the thyrotropic hormone the minimum amount, administered daily in two injections, which will cause a rise of 20 per cent in the metabolism of the hypophysectomized rat by the fourth day. We believe that this unit compares fairly well with the Junkmann-Schoeller unit as determined by the use of the normal guinea-pig, but it has this advantage that the metabolism of the hypophysectomized animal, both before and during treatment, is far less variable than the histologic picture of the guinea-pig's thyroid. The normal guinea-pig thyroid is extremely sensitive to the thyrotropic hormone stimulus, but unfortunately control animals all too frequently, in our experience, have shown mild thyroid hyperplasia.

The thyrotropic principle causes an increase in the excretion of creatine in both the normal and the hypophysectomized rat (Pugsley, Anderson and Collip¹⁴²).

The thyrotropic hormone, like thyroxine, causes an increase in the excretion of calcium by the intestine (Pugsley and Anderson¹⁴³).

Marine and Rosen¹²⁵ produced exophthalmos in the thyroidectomized guinea-pig with acetic acid extracts of anterior pituitary powder. They were of the opinion that the anterior pituitary product stimulated centers in the midbrain controlling the sympathetic innervation of the eye.

A number of workers who have made injections over long periods of anterior pituitary extracts containing the thyrotropic hormone have noted a decrease in the size of the thyroid and a decrease in the metabolic rate of the treated animals (Korenchevsky,¹⁴⁴ Siebert and

Smith,¹⁴⁵ Lee and Gagnon,¹⁴⁶ Verzar and Wahl,¹³⁴ Evans and Sarka¹⁴⁶).

Retrogressive changes in the thyroid of guinea-pigs and ducks treated with anterior pituitary extracts over a long period have been described by Aron,¹⁴⁷ Loeb and Friedman,¹⁴⁸ Schockaert,¹²² Thurston,¹⁴⁹ Friedgood,¹⁵⁰ and Collip and Anderson.¹⁵¹ The latter found by the thirty-seventh day after daily injections of purified thyrotropic extracts that the metabolism of a group of normal rats had fallen 29 per cent below normal, which was approximately the level of metabolism for the hypophysectomized rats of the same colony.

It was shown that the loss of response to the thyrotropic hormone by the rats that had been injected for some weeks was due to the presence in their blood of a specific inhibitory substance. Proof of this was obtained by injecting both normal and hypophysectomized rats with blood serum obtained from the thyrotropic hormone resistant animals. These animals were then shown to be resistant to the injections of known potent hormone extracts.¹⁵²

Blum¹⁵³ described an antithyroid effect of a blood constituent, which he called "katechin." Anselmino and Hoffmann¹⁵⁴ have prepared a lipid fraction from normal blood and tissue which they assert has the physiologic properties of the Blum substance. They report that their blood extract inhibits the thyrotropic hormone as well as thyroxine, and they have also seen an inhibition of the histologic reaction of thyroid hyperplasia in animals injected with thyrotropic hormone and fed the antithyroidin extract. Abelin and Wegelin¹⁵⁵ found that simultaneous injections of diiodotyrosine with anterior lobe extract prevented the marked hyperplasia of the thyroid seen when the latter alone was injected.

The relationship, if any, of this substance of Blum to the thyroid stimulating principle of the anterior pituitary is not clear, but it is obviously a different substance from the antagonist principle found in the blood of thyrotropic hormone resistant animals.

It may be concluded that the thyrotropic principle found in anterior pituitary extracts is an entity having physiologic properties that distinguish it from the

growth factor, the ketogenic principle, the maturity principle, and—as will be seen later—from the adrenotropic hormone

III THE ADRENOTROPIC (INTERRENOTROPIC) PRINCIPLE¹⁵⁰

P. E. Smith^{150a} showed that marked atrophy of the adrenal cortex took place following hypophysectomy in rats and that this degenerative change could be prevented or the normal condition restored by intramuscular implantations of fresh rat hypophyses. Evans¹⁵¹ confirmed Smith's work and reported adrenal cortical repair by the use of purified growth extracts.

In this connection one might call attention to the marked atrophy that follows the destruction of the hypophysis in patients (Fahr,¹⁵⁸ Jaffe and Tannenbergs¹⁵⁹), and to the frequent occurrence of cortical hypertrophy associated with pituitary tumors (Wieth-Pedersen¹⁶⁰), particularly with acromegaly (Salmon¹⁶¹).

In our work it was noted that the adrenotropic effect tended to be associated with thyrotropic effect but that with further purification of the thyrotropic principle the adrenotropic action became less. This led us to attempt to obtain the adrenotropic principle in greater amount and the thyrotropic in less amount by working up the tailings from the thyrotropic extracts. We were in this way successful in obtaining a fraction that was strong in adrenotropic activity and in the doses used was free of thyrotropic effect (Collip, Anderson and Thomson¹⁶²).

There is as yet no satisfactory physiologic test for the adrenotropic principle, for, since the adrenal cortex reacts with hypertrophy after the administration of numerous nonspecific toxins, the results obtained on normal animals (Houssay and his co-workers,¹⁶³ Anselmino and his associates,¹⁶⁴ Emery,¹⁶⁵ Robson and Taylor¹⁶⁶) are not conclusive, and the hormone must always be tested on hypophysectomized animals. However, the observations of Putnam and his associates,¹⁶⁷ who observed real cortical adenomas after the chronic administration of alkaline pituitary extracts, were very suggestive. I also have to mention in this connection the important recent observations of Houssay and his associates,¹⁶⁸ who were able to stimulate the adrenal

cortex of hypophysectomized dogs with pituitary extracts.

No marked effect on the medulla has been described, nor is there any definite evidence of atrophy of the medulla after hypophysectomy, but Houssay and his associates¹⁶³ found a depletion of its epinephrine content after pituitary extract administration in dogs. Two possible effects of the adrenotropic principle, apart from the cortical repair induced in hypophysectomized rats, are (1) a slight decrease in the positive potassium balance of normal animals (Pugsley¹⁶⁹) and (2) an effect on the hemogram. Miss Margaret Hill, who has been making a study of the blood picture as influenced by pituitary extracts, has observed a very definite increase in the reticulocytes when large doses of adrenotropic extracts have been injected daily over a period of weeks. The reticulocyte response appears to follow a definite curve. The significance of this response is not clear as yet.

On theoretical grounds it is conceivable that certain cases of Addison's disease may be due to primary pituitary failure. In this connection it is of interest to mention that in two cases of Addison's disease very marked improvement has occurred when adrenotropic extract was administered. It is, of course, not to be expected that cortical tissue that has been damaged by tuberculosis can be activated by pituitary adrenotropic hormone.

IV THE PARATHYROTROPIC PRINCIPLE

Clinical evidence for an interrelationship between pituitary and parathyroids has been reported by various investigators. The association of parathyroid adenomas with tumors of the pituitary glands was particularly suggestive of such a relationship (Hertz and Krane¹⁷⁰). More recently, several authors have assumed the existence of a special parathyrotropic hormone, the administration of which to normal animals leads to proliferation of the parathyroid cells (Hertz and Krane,¹⁷⁰ Hoffmann and Anselmino,¹⁷¹ Anselmino, Hoffmann and Herold¹⁷²). The recent report by Hertz and Albright¹⁷³ that the urine of patients with hyperplasia of the parathyroids, but not of those with parathyroid adenoma, contains a substance that will produce hyperplasia in the parathyroids of normal rabbits, is of special significance.

EFFECT OF HYPOPHYSECTOMY ON THE PARATHYROID GLANDS

Aschner¹⁷⁴ found no changes in the parathyroids of his hypophysectomized dogs, but Koster¹⁷⁵ states that the parathyroids of hypophysectomized dogs are usually smaller than those of control animals. Houssay and Sammartino¹⁷⁴ frequently found degenerative changes in these glands after removal of the hypophysis, they emphasize, however, that similar changes may also be

156 As Evans (J. A. M. A. 104: 464 [Feb. 9] 1935) has pointed out the principle commonly known in the literature as the adrenotropic is more accurately designated interrenotropic; the present evidence indicates that it stimulates only the adrenal cortex (interrenal gland).—Ed.

observed in the parathyroids of normal dogs. Similarly, P. E. Smith¹⁵ reports parathyroid atrophy after hypophysectomy in the rat.

In our experience, the parathyroids of hypophysectomized rats and dogs show no consistent degenerative changes, even several months after removal of the pituitary. I must say, however, that we made no exact counts of the number of degenerated cells in the glands. The occasional finding of cell groups with pyknotic nuclei in the parathyroids is a physiologic occurrence both in the rat and in the dog and may easily be misleading.

It is of particular interest in this connection that the simultaneous removal of the hypophysis and the pancreas frequently leads to very marked degenerative changes in the parathyroids of the dog, according to Houssay and Biasotti.^{16b} Similar observations have been made in our laboratory. In some cases large areas of the parathyroids became completely necrotic.

EFFECT OF HYPOPHYSECTOMY ON BLOOD CALCIUM

While Gerschman^{17a} found the blood calcium to be normal in hypophysectomized dogs, Geesink and Koster¹⁷ found subnormal values. It should be noted, however, that the latter authors performed their experiments on very young animals, in which the calcium metabolism is always more easily disturbed. In amphibia the blood calcium decreasing effect of hypophysectomy seems to be much more marked than in the higher forms of vertebrates, as judged by the observations of Hogben and his co-workers^{17c} and of Shapiro and Zwarenstein.¹⁸

EFFECT OF HYPOPHYSEAL EXTRACTS ON THE PARATHYROID GLANDS

Hertz and Krane¹⁹ have obtained a fraction, by acid extraction of beef pituitary, that leads to active mitotic cell division and vacuolization of the parathyroid cells in the rabbit. Almost at the same time, Anselmino, Hoffmann and Herold¹⁷² published their results, showing that parathyroid enlargement may be produced in the rat by the administration of a pituitary extract. They attributed this effect to a parathyrotropic hormone (parathyreotropes hormon).

EFFECT OF HYPOPHYSEAL EXTRACTS ON BLOOD CALCIUM

Teel and Watkins¹⁷¹ reported a fall in the blood calcium of the dog after treatment with pituitary fractions containing the growth hormone. Similar

results have been obtained with hypophyseal extracts in rabbits by Hogben and Charles.¹⁸⁰ More recently, Hoffmann and Anselmino¹⁷¹ reported an increase in blood calcium after the administration of their parathyrotropic extract. They concluded that the effect is due to the stimulation of the parathyroids, since their extracts had no effect after parathyroidectomy.

Council on Physical Therapy

THE COUNCIL ON PHYSICAL THERAPY HAS AUTHORIZED PUBLICATION OF THE FOLLOWING REPORT
HOWARD A. CARTER, Secretary

GUIBOR STEREOSCOPIC CHARTS FOR ADULTS AND CHILDREN ACCEPTABLE

The Guibor Stereoscopic Charts, designed for diagnosis and treatment in eye-muscle training, are distributed by Belgard-Spero, Inc., Chicago.

The set consists of fourteen test charts for diagnosis of monocular and binocular vision, fusion amplitude and stereopsis,

The Guibor Stereoscopic Charts

of sixty-six split charts for training of fusion amplitude and stereopsis, and of a holder for the split charts. These charts are made for use with both literate and illiterate patients.

The charts may be used with the ordinary stereoscope which has a 5 prism diopter lens before each eye, the stereocampimeter, the correctoscope, the kratometer, the synoptophore and similar instruments.

These charts provide a means for an intelligent and adequate orthoptic training technique, and objective and subjective examinations. The former is not discussed in the outline accompanying the charts, except to say that the motility, the angle gamma, and the angle of anomaly should be measured. The subjective examination, however, which the designer believes is very important, especially in the latent muscle anomalies, is discussed in detail.

These charts were tested in a clinic acceptable to the Council. The series were reported satisfactory, and the claims made for them conformed with the Official Rules of the Council. The Council on Physical Therapy voted therefore, to include the Guibor Stereoscopic Charts for Adults and Children in the Council's list of acceptable devices.

Council on Pharmacy and Chemistry

REPORTS OF THE COUNCIL

THE COUNCIL HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
REPORTS
PAUL NICHOLAS LEECH, Secretary

CALOMELOL AND CALOMELOL OINTMENT OMITTED FROM N N R

Calomelol, manufactured by the Heyden Chemical Corporation, with its dosage form, Calomelol Ointment, was accepted by the Council for inclusion in New and Nonofficial Remedies in 1909.

As long ago as 1919 the efficacy of calomel munctions for treating syphilis was questioned (Cole, H N, and Littman, Sidney THE JOURNAL, Nov 8 1919, p 1409). This clinical evidence was opposed by Schamberg and some of his co-workers. At a later date, studies on the excretion of mercury following calomel munctions were made (Cole, H N DeWolf H F, Schreiber N E Sollmann, Torald and Van Cleve, Joseph Arch Dermat & Syph 27 1 [Jan] 1933), showing that after 50 per cent calomel munctions the urinary mercury excretion could be best compared to that which occurs after 5 per cent metallic mercury munctions. At the end of four weeks there was a median mercury excretion of but 0.09 mg. The low urinary mercury excretion was explained as due to the difficulty of rubbing the hard particles of mild mercurous chloride into the hair follicles. Calomel munctions are not suitable for treating syphilis.

In view of the foregoing, the Council in its reconsideration of the product at the expiration of the last acceptance period in 1934 voted to omit these products from New and Nonofficial Remedies unless the firm should be able to supply evidence to justify their continued inclusion. The firm replied that it was not in position to supply new and convincing evidence as to the efficacy of Calomelol.

The Council therefore voted to omit Calomelol and its accepted dosage form from New and Nonofficial Remedies.

SHADOCOL NOT ACCEPTABLE FOR N N R

"Shadocol" has been promoted extensively for oral administration in cholecystography by Davies, Rose and Co Ltd Boston. No formula is given on the package nor has any been found in that advertising which forms the basis of this report. However, the labels and advertising do divulge the fact that the preparation contains tetraiodophenolphthalein sodium, the substance for which the Council coined the shorter nonproprietary name tetiothalein sodium. The Connecticut Agricultural Experiment Station in Bulletin 363 (July 1934) reports the following composition (calculated from its analysis):

	per cent
Moisture	16
Sodium tetraiodophenolphthalein	16.7
Lactose	74.2
Anhydrous citric acid	5.3
Undetermined	2.2

It is claimed that this unoriginal mixture is "An improved form of orally administering sodium tetraiodophenolphthalein that 'It is an original product,' that it is 'the result of extensive research' and that it is 'Imitated by others but equaled by none'."

No evidence is presented to substantiate the view that dilution of the essential substance with milk sugar and citric acid gives 'An improved form' of tetiothalein sodium for oral administration, nor is it evident how the product resulting from such dilution can justly be said to represent the result of extensive research.

To avoid the confusion that is caused by the application of different names to the same substance the Council does not recognize proprietary names unless they are applied by the discoverer of an article or by the one who discovers its therapeutic use, or with his consent. When the marketing of a product becomes open to general competition, the Council attempts to coin a convenient title for it adopts this as the

N N R name, and then accepts the marketed brands only if they are offered under the N N R. name or the descriptive chemical name. In the case of tetraiodophenolphthalein sodium the Council adopted the contracted name tetiothalein sodium and adopted tests and standards for the control of products admitted to New and Nonofficial Remedies.

Davies, Rose and Co, Ltd, is not the discoverer of tetraiodophenolphthalein sodium and was not the first firm to make it available for therapeutic use. The marketing of this chemical in admixture with milk sugar and citric acid may not be claimed as a "discovery," nor of such fundamental importance as to justify the application of a special name. The Council is unable to recognize the name "Shadocol."

The addition of lactose and citric acid represents an unnecessary modification which is probably useless except as a commonplace flavor. It is fallacious to consider a modification of this sort as representing "an original product" the result of extensive research, and to claim that it is unequaled by other preparations.

The Council declared Shadocol not acceptable for New and Nonofficial Remedies because it is an unoriginal and unnecessarily complex mixture, marketed with exaggerated claims, under a proprietary, noninformative name, which is also misleading because it implies that the preparation is useful for casting x-ray shadows in general, when in fact the use of its principal ingredient, tetiothalein sodium, is restricted to the biliary tract.

Committee on Foods

THE COMMITTEE HAS AUTHORIZED PUBLICATION OF THE FOLLOWING
REPORTS
RAYMOND HERTWIG Secretary

ACCEPTANCE WITHDRAWN RALSTON WHEAT CEREAL

Manufacturer—Ralston Purina Company St Louis

Description—Essentially whole wheat with coarsest bran removed and added wheat embryo. The wheat embryo content is approximately twice that of whole wheat.

Manufacture, Analysis, and Vitamins—See announcement, THE JOURNAL, July 9, 1932, page 135.

Isolation of Agreement of Acceptance—The company signed an agreement on Feb 2, 1934, to observe the rule of the Committee on Foods to furnish regularly copy of all advertising for review. This rule is essential in order that the Committee may be assured that advertising for accepted foods is maintained in accord with its requirements as published in the Committee's Rules and Regulations and General Decisions. The submission of advertising in this manner involves little expense and does not interfere with the prompt release of advertising. There is no apparent reason why a company using truthful advertising should object to this requirement, and the Ralston Purina Company raised no objection to the rule in order that acceptance of its products might continue. Subsequent to the agreement however, the advertising was not furnished, although the violation of the Committee rule and of the signed agreement was called to the attention of the company.

Discussion of Advertising—Nonsubmitted advertising for Ralston Wheat Cereal in addition, was found to conflict with Committee requirements for good advertising. Some typical false or misleading statements and claims are quoted.

The children are so well since you started them eating Ralston.

It's wonderful to have them glad to eat the cereal child authorities prefer—the one I know is best for them.

In making boys and girls want to eat Ralston Wheat Cereal regularly he has had a splendid influence upon the health and well being of millions of young Americans.

Turning Hero Worship into Health To be like Tom Mix a million more boys and girls began to eat Ralston Wheat Cereal last year.

Now they eat this double-rich hot cereal regularly. Tom Mix has made children everywhere anxious to eat the hot whole wheat cereal which mothers doctors dietitians and teachers prefer for growing boys and girls.

NOW grateful mothers by the thousands write to say, 'It's wonderful what Ralston has done for my children! RALSTON double-rich in vitamin B Does More than Any Ordinary Cereal to Build Strong Bodies.'

Keep Appetites Eager Make Cheeks Rosy Provide Abundant Energy Build Resistance to Colds

and Disease

Remember that—Mother! It's the reason why doctors, dietitians and school teachers in such overwhelming majority prefer this type of cereal—*Ralston Tastes So Good!* You'll be delighted too and genuinely amazed to watch the difference in your child when he has the full value of finest whole wheat to build his body—the double richness in vitamin B to step up his appetite until he's really hungry for the nourishing foods he needs. Every bowlful of Ralston gives your child the full benefit of all the abundant body-building energy producing qualities which make wheat our most important cereal food! And now Ralston does even more for your child! Now it also provides a double quantity of vitamin B—which science tells us has exactly the same effect as sparking western air upon appetites and health. Vitamin B keeps appetites normally eager—makes children want to eat wholesome, necessary foods more satisfying a richer source of quick energy. Do you wonder that children improve when they eat 'double-rich Ralston regularly'? Because cereal is one of the most important foods for growing children an impartial nationwide survey has just been conducted. The sole purpose of the survey was to determine what type of cereal is preferred by authorities on child care. Read the startling results which reveal that 84 out of 100 Child Specialists, 94 out of 100 Hospital Dietitians, 92 out of 100 School Teachers prefer a hot whole wheat cereal enriched with extra vitamin B. Doesn't this overwhelming preference answer any questions you may have about cereals? It proves that double-rich Ralston Wheat Cereal can do far more for your child than any ordinary cereal. How Ralston is Building Better Health and High Ideals among the children of America.

Ralston Wheat Cereal differs from whole wheat in containing less bran but more embryo, it is a good source of food-energy, vitamin B and iron, and a fair source of indigestible bulk. These contributions to the diet warrant emphasis and interpretation in advertising. Instead, the advertising misrepresents the food by presenting it as a special health-food for making children "well" or like Tom Mix (an athletic stalwart hero of the screen) for having "a splendid influence upon the health and well-being of millions of young Americans and about which mothers exclaim 'it's wonderful what Ralston has done for [our] children' for 'build[ing] strong bodies more than any ordinary cereal' for 'keep[ing] appetites eager mak[ing] cheeks rosy, provid[ing] abundant energy build[ing] resistance to colds and disease. Neither Ralston itself any other single food nor the entire well balanced diet possesses these potencies. Ralston cannot do these things claimed for it.

It is alleged that child authorities, doctors, dietitians, teachers "prefer Ralston," "prefer this cereal for growing boys and girls" or "in such overwhelming majority prefer this type of cereal." There are no authentic data showing that these professions prefer this food. The vagueness of such claims permits false interpretations that the product has been officially selected by the professions as superior to other cereals.

It is alleged Ralston is "double-rich," another type of claim which is misleading because of vagueness. The manner in which it is "double-rich" should be explicitly stated. The vitamin B content will not in any general sense step up the appetite, "have the same effect as sparking western air upon appetites and health," "keep appetites normally eager or make children want to eat wholesome necessary foods." It has not been shown that 'Ralston can do far more for your child than any ordinary cereal. Lag in appetite may be due to many other causes than just insufficiency of vitamin B in the diet.

The advertising is false and misleading a discredit to the product and to the company. Advertising standards in general are disrupted and lowered by advertising of this character. Ralston Wheat Cereal will therefore no longer be listed among the products accepted by the Committee on Foods.

ACCEPTANCE WITHDRAWN

WHEATENA

Manufacturer—The Wheatena Corporation, Wheatonville, Rahway N J

Description—Toasted granular wheat cereal composed essentially of the endosperm, the major portion of the bran and the embryo of red winter wheat. See announcement of acceptance, *THE JOURNAL*, May 2, 1931 page 1478.

Acceptance Withdrawn—The manufacturer is not willing to furnish the Committee with copy of all pieces of new advertising in accordance with the requirement of its Rules and Regulations. Regular submission of advertising is necessary to assure the Committee that its requirements are being fulfilled. There is no apparent justifiable reason why the manufacturer of an accepted food who is using truthful and proper advertising should not be willing to furnish copy of all pieces of

advertising, involving only nominal expense and time, for review by the Committee.

Since the manufacturer of this accepted food is not willing to comply with this simple requirement to assure that the advertising is being maintained acceptable, acceptance has been withdrawn.

ACCEPTED FOODS

THE FOLLOWING PRODUCTS HAVE BEEN ACCEPTED BY THE COMMITTEE ON FOODS OF THE AMERICAN MEDICAL ASSOCIATION FOLLOWING ANY NECESSARY CORRECTIONS OF THE LABELS AND ADVERTISING TO CONFORM TO THE RULES AND REGULATIONS. THESE PRODUCTS ARE APPROVED FOR ADVERTISING IN THE PUBLICATIONS OF THE AMERICAN MEDICAL ASSOCIATION AND FOR GENERAL PROMOTION TO THE PUBLIC. THEY WILL BE INCLUDED IN THE BOOK OF ACCEPTED FOODS TO BE PUBLISHED BY THE AMERICAN MEDICAL ASSOCIATION. **RAYMOND HERTWIG** Secretary

IRRADIATED VITAMIN D PASTEURIZED MILK

Distributors—

Beatrice Creamery Company, Denver (Meadow-Gold)
Beatrice-Meadow Gold Dairies, Inc. (Champaign Sanitary Milk Division) Champaign, Ill (Meadow-Gold)
Dixie Dairy Company Gary, Ind
Grisham Ice Cream Company, Corpus Christi, Texas
W D F Hayden Dairy Company, Dover, N H
Hutt's Dairy, Buffalo Tonawanda, North Tonawanda and Amhurst, N Y (Bottler—Wm Weckerle & Sons, Buffalo)
Iowa Farms Milk Company, Davenport, Iowa
Kleinheinz Dairy Company, Wausau, Wis
Modern Dairy Company, La Crosse, Wis
Prairie View Dairy Company, East Chicago, Ind
Richmond Dairy Company, Richmond, Va
The Supreme Dairy Company, Denver (Superb Quality and Supreme Quality Guernsey)
Thompson's Dairy Washington, D C
Urbana Pure Milk Co., Urbana, Ill
Virginia Dairy Company, Richmond, Va

Description—Bottled pasteurized vitamin D milk irradiated with ultraviolet rays.

Preparation—The milk complies with legal requirements and is pasteurized by the standard holding method. For description of irradiation, see *THE JOURNAL*, Oct 7, 1933, page 1155.

Vitamins—Clinical investigation shows this milk to be a reliable antirachitic agent if the proper amount is used. Contains 135 U S P X (Revised, 1934) vitamin D units per quart.

Claims of Distributors—Irradiated antirachitic pasteurized milk having otherwise the flavor and food values of usual pasteurized milk.

WARRANTY SIEVED CARROTS

Manufacturer—The Nielsen Corporation Ltd, Oakland, Calif

Description—Sieved carrots prepared by efficient methods for retention in high degree of the natural mineral and vitamin values. No added sugar or salt.

Manufacture—The carrots as received from the field are sorted, trimmed, thoroughly soaked, washed with a brush washer, and subsequently processed and canned by essentially the same procedure as described for Warranty Sieved Spinach (*THE JOURNAL*, Feb 2, 1935, p 399).

Analysis (submitted by manufacturer) —

	per cent
Moisture	88.9
Total solids	11.1
Ash	0.8
Sodium chloride	0.06
Fat (ether extract)	0.1
Protein (N x 6.25)	1.0
Reducing sugars as invert sugar	3.3
Sucrose	
Crude fiber	0.7
Carbohydrates other than crude fiber (by difference)	8.5

Calories—0.4 per gram 11 per ounce.

Retention—The method of preparation and processing insures the retention in high degree of the natural vitamin values.

Claims of Manufacturer—Specially intended for infants, children and convalescents, and for special smooth diets. Only warming is required for serving.

SATURDAY, MARCH 16, 1935

COMPARISON OF MATERNAL DEATHS

Statistical inquiries perhaps are frequently viewed with more respect than may actually be warranted. When applied to medical subjects, statistics have the same significance as the X-rays; they are a means to an end, not an end in themselves. Thus the now numerous statistical studies dealing with maternal mortality must be analyzed as a laboratory test would be rather than serving merely as a basis for recriminations. The lesson of essential importance is not that the maternal mortality rate is higher in one country or district than another but that certain factors influence the death rate from this cause and that some of them may be favorably affected by the knowledge gained from statistical analysis.

In order to serve a useful purpose therefore statistics, like laboratory tests, must be both accurate and understood. The factors influencing the accuracy of vital statistics are twofold. The first of these is the clinical ground work. Without exact and uniform clinical diagnoses, statistical analysis is without value. This factor is well known, and exhaustive efforts to establish a firm clinical foundation¹ have been made in most studies. The other important element is the manipulation and interpretation of the statistical data obtained. This work is highly technical and requires special training in biometrical methods. Even when so applied, the modifying factors are so numerous and complicated that the apparent conclusions may not be real in fact.

One of the criticisms that have been applied to maternal mortality statistics is that the methods of assigning the cause of deaths associated with pregnancy and childbirth are different in different countries. The statistical comparability would naturally be greatly impaired by any differences of this character. This problem of classification of maternal deaths, however,

has been recently investigated.² In order to obtain data that would throw light on the effect of differences in assignment procedure on the comparability of maternal mortality rates, it was planned to send to the bureaus of vital statistics in the principal foreign countries the pertinent information from 1,073 United States death certificates for 1927 on which pregnancy or childbirth was mentioned. It was to be requested that each office mark each death as puerperal or nonpuerperal according to its own method of assignment of cause. Actually, because of duplications, 477 certificates, selected to include at least one death of every type in the sample, were transmitted to twenty-four foreign countries. The information from these certificates, set up in list form with each line representing one death, consisted of the case number, age of the mother, primary and contributory cause of death, and performance or nonperformance of an operation and of a necropsy. It was asked that the first of these columns be checked if the death would be classed as puerperal and the second if it would be classed as nonpuerperal by the statistical bureau in charge of coding cause of death in each country. No information was given with regard to the cause assigned in the United States. On the return of the lists from sixteen countries the 596 deaths in the original group not sent abroad were reclassified as puerperal or nonpuerperal in accordance with the assignments made by the foreign countries for those which had been transmitted. The groups of deaths were then thrown together and a tabulation of the 1,073 certificates was prepared showing the assignment as made by the United States Bureau of Census and as puerperal or nonpuerperal by each foreign bureau that complied with the request. The proportions assigned to puerperal and nonpuerperal causes in the United States were not significantly different from those for Australia, the Netherlands, New Zealand and Scotland. Italy, Canada, Chile, Czechoslovakia, Northern Ireland, France, Irish Free State, Sweden, Estonia, England and Wales, and Norway assigned significantly more to nonpuerperal and significantly less to puerperal causes than the United States. Denmark was the only country that assigned more of the deaths to puerperal causes than the United States.

The rates for the United States were reclassified on the same basis of assignment of cause as that made in each of the foreign countries. When this was done and a comparison made, the United States rate was still in excess of the official rates of the respective countries with one exception (Scotland). After adjustment of assignment procedures the United States rate exceeded the official rates of five countries (Norway, Sweden, France, Italy and the Netherlands) by at least 100 per cent. The best position which the United

¹ New York Academy of Medicine. Hooker, R. S., Director. Maternal Mortality in New York City. New York, the Commonwealth Fund, 1933. Philadelphia County Medical Society. Williams, P. F., Chairman. Maternal Mortality in Philadelphia. Philadelphia County Medical Society, 1934.

² Tandy, Elizabeth C. Comparability of Maternal Mortality Rates in the United States and Certain Foreign Countries, Children's Bureau U. S. Department of Labor Publication 229, 1935.

States could have achieved was fifth from the highest when its rate was determined under the system of Norway and of England and Wales.

As pointed out in the report, the number of death certificates in the group sent abroad was too small to warrant final conclusions regarding the assignment procedure of the countries from which returns were received. The study does indicate, however, an effort to refine and make comparable the maternal mortality statistics of different countries. As pointed out previously, however, only a few of the factors involved are corrected by this comparison.

THE GAPS IN SICKNESS INSURANCE PROPAGANDA

The writings on sickness insurance that have appeared in the United States during the last twenty years are marked by a monotonous sameness. While they purport to be based on scientific analyses and accurate descriptions of existing systems, the sources from which they draw their information lead to this impression of similitude. Practically all the references concern the publications of insurance carriers or reports by government employees in nations having sickness insurance or to other writers who have used these sources. In every country, at the same time, there has been an almost equally extensive literature, consisting of books and pamphlets by physicians practicing under insurance. The medical journals in these countries contain frequent discussions of the workings of sickness insurance, yet it is hard to find reference to any of these medical writings in any of the books or articles published by propagandists in the United States. They seem to avoid studiously any references to the literature of the opposition.

Advocates of insurance give but slight mention to the characteristics of the medical service furnished under insurance, yet the expressed objective of service systems of insurance is to provide a medical service for the insured.

Discussions of movements in morbidity rates, under insurance, are avoided. Yet again sickness insurance is offered primarily as a means of reducing the suffering from illness. The question is seldom raised in such writings as to whether the actual effect of insurance is to reduce the amount of illness and the consequent suffering and rate of mortality.

A strange silence prevails on the relation of insurance to preventive medicine, although there is much theorizing on the possibility of preventive care under insurance. When the actual works of insurance systems are being discussed, however, there is complete absence of data indicating the extent to which preventive medicine is practiced. For example, advocates of sickness insurance do not discuss the extent of immunization against diphtheria under insurance or the mortality rate from this disease as compared with non-

insurance countries. Neither do they speak of the number of periodic health examinations under insurance. They are, in fact, ominously silent on comparisons of the percentage of tuberculous, cancerous or diabetic diseases that are detected at an early stage as contrasted with similar figures in the United States in private practice.

It is useless to search the propaganda of sickness insurance for information on the progress of medical science, medical education and graduate training under insurance systems, nor will any explanation be found of why the nations that led the world in these fields at the time insurance was introduced have been outdistanced, in little more than a generation, by nations in which private practice has been retained.

Although the most important function of medical care and medical science is to extend the period of human life, no exponent of sickness insurance has ever compiled, or at least published any comparative mortality tables showing the relation of insurance to the duration of human life.

Moreover, the propagandists overlook the fact that, in nearly every country with a system of sickness insurance, numerous critics demand a transformation. In Germany, the home of the oldest sickness insurance system, a movement has been growing for many years to abolish the insurance system in favor of some compulsory saving.

In reciting the history of sickness insurance the propagandists are inclined to suppress the fact that it was introduced in most instances against the opposition of the workers who were to receive the services and at least the sharp criticism of the physicians who were to give the service. In some sections of Germany, England and France, workers' opposition led to almost violent resistance.

Today there are numerous extensive experiments in forms of sickness insurance in the United States. Although the propagandists of sickness insurance claim credit for the introduction of workmen's compensation, which now provides an insurance medical service as large as that of many European systems, little or no reference is made by sickness insurance advocates to the character of the medical service supplied under compensation laws. They seldom quote from legislative and other investigations of that service. They are strangely still on the operations of the "compensation clinics" in New York City or the conditions that have arisen in such states as Washington and West Virginia. They never mention the fact that, wherever medical service under compensation is satisfactory, this result is due to the strenuous efforts of the state medical societies.

These are not mere oversights or casual omissions. They are vital points in the discussion of sickness insurance. Some propagandists avoid them, and thus the propaganda misleads and misinforms the reader.

THE PHYSIOLOGY OF THE PHOSPHOLIPIDS

The fact that the phospholipids are constituents of all living material has given rise to the belief that these substances play some fundamental part in the structural make up and in the vital activity of the cell. Several theories of the physiologic function of the phospholipids have been proposed, however, modern students¹ of the problem appear to endorse only three of these, the metabolic theory, the oxygen transport theory and the structural theory. According to the metabolic theory the phospholipids, particularly the lecithins, are important intermediary products in the metabolism of fats and fatty acids, serving as a means for the transport and oxidation of otherwise water-insoluble, stable fatty acids. Neutral fat from the various depots or from the gastro-intestinal tract is carried to the liver, where desaturation of a portion of the fatty acids occurs and phospholipids are formed. The phospholipids are then transported by the blood to the tissues, where the fatty acids are released and oxidized. Not all of the available evidence, however, supports such a hypothesis. The striking constancy of the phospholipid content of certain organs, even in the face of sudden and extreme changes in metabolism, and the fact that each organ of the body possesses a characteristic phospholipid content which has no apparent relationship to the intensity of fat metabolism, are examples of well established facts that do not fall in line with the metabolic theory. The view is held by some investigators that the phospholipids may be concerned in the transport of oxygen by virtue of the double bond linkages within the molecule, which may act as oxygen accepters as well as potential hydrogen accepters. Although there is some *in vitro* evidence supporting this hypothesis, such a function of phospholipids has not been demonstrated under physiologic conditions. The third hypothesis, the structural theory, proposes that the phospholipids, because of peculiar physicochemical properties, are important elements in the constitution of protoplasm and in the construction of the membrane enveloping the cell. Experimental evidence in support of this theory is still scanty. Thus, at present definite conclusions regarding the physiologic function of the phospholipids cannot be drawn.

Apparently, phospholipids are readily synthesized by the animal organism. They are present in the bodies of rats, for example, which have been maintained on diets containing only neutral fat as the source of lipid. Also the eggs of ducks or hens fed a ration deficient in phospholipids are known to contain the usual amounts of these substances.

The phospholipid content of different organs is rather characteristic of the organ, within limits, of the species concerned. Brain and liver contain the largest amount, the pancreas, kidneys and muscle containing

somewhat less. According to a recent report² the phospholipid content of various muscles varies directly with activity and resistance to fatigue. Rabbit heart muscle, for example, contains nearly four times as much phospholipid as the gastrocnemius muscle.

Physiologic factors such as diet, activity, age and certain hormones are known to affect the phospholipid content of tissues, although in general the variations are not large. Fasting appears to decrease muscle phospholipid, to increase liver phospholipid and to have no effect on brain phospholipid. Diets containing relatively large amounts of fat or carbohydrate increase the phospholipid content of the liver and of the blood. Physiologic activity itself affects the phospholipid content of the tissue concerned, an increase in activity eliciting an increase in this substance. The phospholipid content of tissues, particularly of the blood, may show decided changes in certain diseases. Increased blood phospholipid is encountered in diabetes, nephrosis, chronic hemorrhage, Niemann-Pick's disease, epilepsy, hypertension, syphilis, hypothyroidism, liver injury by phosphorus and by chloroform, hydrophobia and B-avitaminosis. Decreases in the phospholipid content of the blood are usually found in infectious fevers, cancer, epilepsy and pernicious anemia. In contrast to the content in the blood in diabetes, the phospholipid content of portions of the femoral nerves of diabetic patients, according to recent analyses,³ is much lower than that of similar specimens from normal subjects. Furthermore, as the clinical signs of neuropathy progressed the degree of lipid deficiency increased. The relation appears to be quite the opposite in cases of cancer, the blood phospholipid being less than normal whereas the phospholipid content of the malignant tumor is high. The elucidation of the significance of these interesting observations may well yield information of value not only in determining the nature of the changes occurring in these diseases but also in the ultimate solution of the important question of the physiologic function of the phospholipids.

Current Comment

COD LIVER OIL

Cod liver oil has long held a prominent place among therapeutic agents. Despite studies that have revealed the enormously greater antirachitic potency of viosterol as gaged by the conventional bio-assay methods, cod liver oil is still highly regarded. There is evidence that, based on units of vitamin D as determined by assay on rats, cod liver oil is superior to viosterol in the cure and prevention of rickets in human infants. There has accumulated a considerable mass of experimental proof

that leg weakness in chickens is far more susceptible to cure and prevention by cod liver oil than by viosterol in oil in amounts of each equally efficacious in the cure of rickets in rats. Despite the fact that nearly all fish oils contain vitamin D, perhaps the most striking support for the peculiar efficacy of cod liver oil has been recently brought forward by Bills, Massengale and Imboden,¹ who found that blue fin tuna liver oil with 40 000 units of vitamin D per gram was only one sixth as effective when assayed with chicks as was cod liver oil with only 100 units of vitamin D per gram. These and other observations have suggested that there are several forms of vitamin D. However, apart from the vitamin content, cod liver oil has other chemical attributes, as has been emphasized by Holmes and Remington.² These investigators have shown that American cod liver oil contains more iodine than do most ordinary foods (calculated to the dry basis). The content of iodine varies with the place where the fish are caught, the average of the values being nearly 9 parts per million. It is further pointed out that, accepting the daily iodine requirement for man as between 50 and 100 micrograms 10 cc of high grade medicinal cod liver oil would, if thoroughly assimilated, contribute to the daily iodine requirement. From this analysis it is not to be concluded that cod liver oil should be administered for its iodine content.

CONTINUOUS CAMPAIGN FOR IMMUNIZATION AGAINST DIPHTHERIA NECESSARY

A movement of interest to physicians will be announced during the month of April by the May Day Committee of the State and Provincial Health Authorities of North America, together with the American Child Health Association, as the May Day-Child Health Day Project for 1935. A determined effort will be launched to promote diphtheria immunization. According to notifications sent to national health organizations and to the press, the objective was chosen because there has been no reduction since 1930 in the number of deaths from diphtheria throughout the United States. Some states have accomplished a notable reduction in the number of deaths, therefore it must follow that others have suffered increases. This means that diphtheria immunization in the United States has not been uniformly and consistently applied. The committee announces its belief that immunization should be the work of the private physician. State health officers will be asked to send a communication to each physician in the state urging (1) that he remind his patients who have children under school age of the need for immunization, (2) that he ask his patients to bring their children to be immunized, and (3) that he make it a routine of his practice in the future to immunize during the first year of life all babies under his care. The medical profession, which has never been enthusiastic about sporadic health drives, may well support this effort, which uses May Day merely as a taking off

place and a means of attracting the attention of the public. The objective of the plan is to immunize all children between the ages of 6 months and 6 years and to maintain this as a continuing service. It is hoped that cooperation will be developed in the states between the departments of public health and the medical profession, since both agencies are necessary for the success of any community plan for diphtheria control. The Board of Trustees of the American Medical Association, on request of the American Child Health Association, urges physicians to assist and cooperate in this plan.

Medical Economics

MEDICAL CARE OF THE INDIGENT IN THE DISTRICT OF COLUMBIA

The Medical Society of the District of Columbia, June 2, 1934, adopted a set of principles indicating policies to be pursued in any plan for providing medical care for the indigent sick. This statement has been forwarded to all agencies concerned with the furnishing of such medical care and is to form the basis of future actions by that society.

As examples of previous and present cooperation in general health activities, the statement instances the work of the medical society in health education, tuberculosis care, restricting the practice of medicine by hospitals, and guiding the movement for group hospitalization so as to safeguard against any harmful features. At the present time the society is studying, through appropriate committees, methods of setting up an agency to secure medical service by affording an opportunity to budget the cost of medical care. It is also working on a plan to safeguard the right of an employee under workmen's compensation to be treated by a physician of his own choice.

Those needing medical care may be divided into three groups.

(a) Those able to pay for such care out of their own resources.

(b) Those who might be able to pay for care themselves if means should be provided to spread the payment over a sufficient length of time.

(c) The group whose members are without resources to meet the needs of medical care.

Special provisions are required for only the last two groups. The first step is to insure that funds available are used economically and appropriately for the benefit of the truly indigent. The executive committee of the Community Chest has established a central admitting bureau, which is endorsed by the medical society as an effective and forward step in preventing the abuse of medical charity.

In considering the problem of the indigent, it is noted that the physicians of the United States contribute to the sick poor services valued at a million dollars daily. The present government contribution for this purpose is largely represented by ten physicians to the poor at a salary of \$1 a day, less 10 per cent. It is obvious that such a plan leaves medical care of the indigent almost entirely to the charity of the local profession.

This is a situation in which any agency planning medical care for the indigent is preparing to give away medical services which it does not possess and for which it does not, and apparently cannot, pay. Until such time as such agencies are in a position to pay for the services of physicians at mutually agreeable rates the medical profession is entitled to determine the conditions under which it is willing to furnish medical care to the indigent.

The medical society, therefore, as one of the representative organizations of the local profession, by the adoption of this resolution and statement gives notice that any commitments for the disposal of free medical services arrived at by individuals, groups, committees or any agencies, official or unofficial, to whose deliberations it has not been a party, are without binding effect upon it or its members and, in any event, remain entirely subject to its approval or disapproval.

1. Bills, C. E., Massengale, O. N. and Imboden. *Minam. Science* 80: 596 (Dec. 21) 1934.
2. Holmes, A. D. and Remington, R. E. *Iodine Content of American Cod Liver Oil* *Am. J. Dis. Child.* 49: 94 (Jan.) 1935.

The only object of the medical society in making this statement is to promote an accord between all the agencies responsible for furnishing medical care to the indigent and to secure cooperation and understanding rather than friction and discord in order that no deserving individual in need of care shall go without it

Association News

MEDICAL BROADCASTS Columbia Broadcasting System

The American Medical Association broadcasts on a western network of the Columbia Broadcasting System each Thursday afternoon on the Educational Forum from 4 30 to 4 45 central standard time. The next three broadcasts will be delivered by Dr W W Bauer. The titles will be as follows:

March 21 Rickets
March 28 This Is No April Fool
April 4 Negro Health Week.

National Broadcasting Company

The American Medical Association broadcasts under the title "Your Health" on a Blue network of the National Broadcasting Company each Tuesday afternoon from 4 to 4 15 central standard time. The next three broadcasts will be as follows:

March 19 White Collar Hazards W W Bauer M D
March 26 Tonics and Sedatives Morris Fishbein M D
April 2 Sickness Insurance R G Leland M D

Medical News

(PHYSICIANS WILL CONFER A FAVOR BY SENDING FOR THIS DEPARTMENT ITEMS OF NEWS OF MORE OR LESS GENERAL INTEREST SUCH AS RELATE TO SOCIETY ACTIVITIES, NEW HOSPITALS, EDUCATION, PUBLIC HEALTH, ETC.)

ARIZONA

Bill Introduced—S 167, to amend the medical practice act, proposes (1) to eliminate the provision that of the members of the board of medical examiners two shall be allopaths, one homeopath, one eclectic and one osteopath by requiring four members of the board to be graduates of schools recognized by the American Association of Medical Colleges and one member to be a graduate of a recognized school of osteopathy (2) to provide staggered six year terms for members of the board (3) to make it a felony for any one to practice or attempt to practice without being licensed and (4) to require licensed physicians and osteopaths to register annually on or before the first day of January with the secretary of the board and at that time to pay a fee of \$3.

ARKANSAS

Bills Introduced—S 442 to amend the medical practice act, proposes to authorize the boards of medical examiners to license without examination applicants who are diplomates of the National Board of Medical Examiners. H 486 to amend the osteopathic practice act, proposes to prohibit osteopaths from performing major surgical operations but to permit them to practice osteopathy in all the subjects or branches on which they were examined when they applied for licenses. The bill further proposes to permit osteopaths to make and sign birth certificates, death certificates and/or all other certificates pertaining to public health.

COLORADO

Personal—Dr Charles J Kaufman formerly of New York, was recently appointed medical director of the National Jewish Hospital, Denver and assistant professor of medicine at the University of Colorado School of Medicine.

Society News—The Boulder County Medical Society was addressed in Boulder February 14 by Drs Robert K. Dixon and Louis S. Faust, Denver on "Diagnosis and Management of Upper Abdominal Complaints" and "Diarrhea in Adults" respectively. A symposium on cancer of the gastro-intestinal

tract was presented before the Northeast Colorado Medical Society in Sterling, January 10, by Drs Kenneth D. A. Allen, Constantine F. Kemper, George B. Kent and George Z. Williams, all members of the cancer team of the state medical society. Dr William Senger, Pueblo, addressed the Pueblo County Medical Society, January 22, on "Tumors of the Breast."

Bills Passed—The following bills have passed the house and the senate. H 138, proposing to repeal the laws regulating the sale, distribution or possession of narcotic drugs and to enact what appears to be the uniform narcotic drug act and H 557, proposing to prohibit the retail sale or distribution of barbitol or other hypnotic or somnifacient drugs except on the prescription of a duly licensed physician, dentist or veterinarian. S 228 has passed the senate proposing to make it the duty of any physician, nurse or midwife, assisting in or in charge of the birth of any infant or having its care after birth to treat its eyes as soon as possible after birth with a prophylaxis approved by the state board of health.

CONNECTICUT

Dr Greenburg Appointed Health Officer—Dr Leonard Greenburg, acting health officer of New Haven has been placed in full charge of the department of health. He succeeds Dr John L. Rice, who left New Haven to become health officer of New York City. Dr Greenburg, assistant clinical professor of public health at Yale University School of Medicine succeeded Dr Herbert R. Edwards as acting health officer when the latter resigned to direct the tuberculosis program in New York under Dr Rice. In 1923 Dr Greenburg received the degree of doctor of philosophy from Yale University and in 1930 the degree of doctor of medicine. He was a member of the staff of the U. S. Public Health Service from 1918 to 1922.

DELAWARE

Bill Introduced—S 155 proposes to prohibit any child from attending either a public or a private school unless it has been successfully vaccinated against smallpox or produces a certificate from a practicing physician that vaccination is inadvisable by reason of some physical disability.

Society News—Dr Joseph B. Wolfe, associate professor in medicine and director of the cardiovascular department, Temple University School of Medicine, Philadelphia, addressed the New Castle County Medical Society February 19 in Wilmington on "New Concepts in the Treatment of Angina Pectoris and Intermittent Claudication."

DISTRICT OF COLUMBIA

Medical Bills in Congress—S 2153, introduced by Senator Copeland, New York, proposes to provide for the prevention of blindness in infants born in the District of Columbia.

Graduate Clinic—The third annual graduate clinic of George Washington University School of Medicine Washington was held, February 23. Sessions were held at the Garfield Memorial Hospital and the school of medicine. The following subjects were presented:

Uterine Cervical Stump Pathology Dr Henry L. Darner, associate in obstetrics and gynecology.

Head Injuries Dr Harry H. Kerr, clinical professor of surgery.

Some Unusual Nephropathies Dr Henry C. Macatee, clinical professor of pediatrics.

Cancer of the Prostate Dr Francis R. Hagner, professor of urology.

Management of Unusual Fractures of the Femur Dr Custis L. Hall, assistant professor of surgery.

Cystoscopic Demonstrations Drs Homer G. Fuller, clinical professor of urology, Alan J. Cheney, associate in urology and Charles P. Howze, associate in urology.

The Routine Treatment of Gonorrhea in Women (The Nonantisepic Method) Dr Bernard Notes, clinical instructor in obstetrics and gynecology.

Methods of Immunization Against Poliomyelitis Dr Earl B. McKinley, dean of the medical school.

Surgical Edema Dr Charles S. White, professor of surgery.

Endocrinology in the Treatment of Functional Disorders of the Female Dr Jacob Kotz, clinical professor of obstetrics and gynecology.

In the afternoon the guests inspected the laboratories and demonstrations at the school of medicine.

Society News—At a joint meeting of the ophthalmologic and otolaryngologic sections of the Baltimore City Medical Society with the Medical Society of the District of Columbia, February 15, in Washington speakers were Drs William H. Wilmer on "Pits or Holes in the Optic Disk," Walter A. Wells "Something About the External Nose," Oscar Wilkinson "Treatment of Ocular Injuries" and Frederick C. Schreiber "Septic Meningitis." Dr Douglas Quick, New York, addressed the district society, March 13, on "Treatment of Cancer of the Breast." The George M. Kober Medical Society was addressed January 21, by Dr Russell J. Fields on "Incidence of Syphilis in Washington" and Otto

Wendt, D.D.S., "Retention of Teeth Following Fracture"
—Speakers before the Osler Medical Society, January 21, were Drs Eugene Clarence Rice Jr., on "Meningitis in Children," and James M Tadeley, "Urethral Calculus"

FLORIDA

Personal—Dr William J Lancaster, Tampa has been appointed superintendent and medical director of the Atlantic Coast Line Railroad. He took over his new position, January 1 with headquarters at Wilmington, N. C. The Hillsborough County Medical Society gave a dinner in honor of Dr Lancaster, January 3, and presented him with an engraved watch.—Dr and Mrs Thomas S Anderson Live Oak, celebrated their golden wedding anniversary, Dec. 17, 1934.—Louva G Lennert, chief engineer of the state board of health since 1932 has been named assistant state director of malaria control and sanitation. Mr Lennert has served with the board of health of Texas and California, the Rockefeller Foundation, and the public health service in Texas and Louisiana, newspapers reported

GEORGIA

Society News—Dr Jack C Norris, Atlanta, presented a paper on 'The Pathology of Agranulocytosis—A Survey of Seventy-Three Cases' before the Fulton County Medical Society, February 7. Dr Emmett D Highsmith, Atlanta presented a paper on "The Possibilities of Plastic Surgery," before the society, February 21.—The Fulton County Medical Relief Association recently changed its name to the Atlanta Medical Service Bureau.—Speakers before the Fourth District Medical Society in Griffin February 6, included Drs Charles E Irwin, Warm Springs, on 'After Care of Poliomyelitis', George L. Walker, 'Practical Management of Congestive Heart Failure', James E Paulin, 'Medical Economics,' and Allen H Bunce, 'Transfusion in the Treatment of Infectious Arthritis,' all from Atlanta.—Dr Job C Patterson, Cutlbert, read a paper on 'Duodenal Stasis' before the Randolph County Medical Society in Cutlbert February 7.—Dr Hyland F Bent, Midville discussed 'Uterine Hemorrhage at the Menopause' before the Burke-Jenkins-Screven Counties Medical Society at Millen, February 7.

Bills Introduced—H 752, to amend the chiropractic practice act, proposes to require chiropractors to register annually, on or before April 1 with the joint secretary of the examining boards and at that time to pay a fee of \$5. Failure on the part of a chiropractor to register annually is automatically to revoke his license. S 197 proposes to permit any hospital not solely maintained by public funds, which is approved by the American Medical Association, the American Hospital Association, the American College of Surgeons, the Medical Association of Georgia, or the Georgia Hospital Association to enter into contracts to provide hospitalization in consideration of a stipulated amount of money to be collected weekly, monthly or yearly in advance. Substitute for H 365 proposes to prohibit the retail sale or distribution of barbituric acid, amylal alonal, luminal, veronal or sodium amylal except on the prescription of a licensed physician, dentist or veterinarian. H 695 proposes to make it unlawful for any person other than a registered pharmacist to sell or offer for sale any prophylactic, contraceptive or chemical or mechanical instrumentality or agency for the prevention of conception or of venereal diseases.

ILLINOIS

Bills Introduced—H 411 and S 210 propose to impose on physicians, osteopaths, dentists, chiropractors, chiropodists and optometrists an annual occupational tax equal to 3 per cent of their gross receipts from practice. H 425, to amend the medical practice act, proposes to permit corporations to practice medicine.

Chicago

Hospital News—A new \$500,000 addition to the U. S. Marine Hospital Chicago, was dedicated, February 18 with Surg. Gen. Hugh S. Cumming presiding at the ceremonies. The new wing which contains 109 beds increases the institution's capacity to 264 beds. The hospital was founded in 1873.

Course in Tumor Pathology—It is announced that the membership quota for the course in tumor pathology that is being given at the Cook County Graduate School of Medicine has been reached, and no further applications will be accepted. The course which is under the direction of Dr. Richard H. Jaffe will be repeated in the fall.

Focal Infections—"The Present Concept of Focal Infection" will be discussed by Drs. Isidor Pilot and Joseph L. Miller

before a joint meeting of the Chicago Medical Society and the Chicago Society for the Study of Rheumatic Diseases, March 20. Dr. Edward H. Ochsluer will present a paper on "The Value of Colloidal Gold in Inoperable Cancer."

Reference Bureau—The Chicago Medical Society has placed in operation a reference bureau for the public. General practitioners and specialists are classified and indexed according to the branch society of which they are members. Physicians belonging to the bureau will be called in rotation. Formerly when calls for a physician came to the society they were denied, but now under the new service an inquirer will be referred to a physician in his own residential district. No charge will be made for the service, only the attending physician receiving a fee.

Society News—The Chicago Orthopedic Society was addressed, March 8, by Drs. Max Cutler on 'Treatment of Bone Tumors' and Charles W. Peabody, Detroit, "Tendon Transplants Judged by Late Results."—At a meeting of the Chicago Urological Society, February 28, Drs. Tyrrell G. McDougal and Julius M. Glasser discussed "Conservative Treatment of Hydronephrosis" and "Calculi Formation Following Prostatectomy," respectively.—Speakers before the Chicago Council of Medical Women March 1, were Drs. Ethel M. Davis, "Rheumatic Endocarditis in Children," and Alice K. Hall, "Popular Fallacies in Otolaryngology."—Among others, Dr. Owen H. Wangerstein, Minneapolis, addressed the Chicago Surgical Society, March 1, on "Practical Aspects of the Therapeutic Problems in Bowel Obstruction."—The Chicago Laryngological and Otolological Society was addressed, March 4 by Dr. William F. Petersen, on 'Meteorological Factors in Otolaryngologic Practice.'

INDIANA

Reciprocity with New York—Reciprocity relations for licenses to practice medicine have been established between Indiana and New York, according to the *Journal of the Indiana State Medical Association*.

Society News—Dr. George Gilbert Smith, Boston, spoke before the Indianapolis Medical Society, February 19, on 'Renal Infections', he also conducted a clinic. A symposium on coronary disease was presented before the society, February 26, by Drs. George S. Bond, Robert M. Moore and Cyrus J. Clark, Indianapolis.—Speakers before the Northeastern Indiana Academy of Medicine at Kendallville, February 21, were Drs. John W. Thomson, Garrett and Abraham J. Sparks, Fort Wayne, on 'Rupture of the Liver' and 'Transurethral Prostatectomy,' respectively.

Bill Introduced—S 229 proposes to create an independent board of chiropractic examiners and to regulate the practice of chiropractic. "Chiropractic," states the bill, 'is a Philosophy, Science and Art of things natural, a system of locating and removing interference with nerve transmission and expression and its effects by adjustment of the articulations of the spinal column and adjacent tissues for the correction of the cause of disease and includes physical, hygienic and sanitary measures incident thereto. A license to practice Chiropractic shall not confer upon the licensee the right to prescribe drugs, practice surgery or obstetrics, or to administer anaesthetics.'

IOWA

Baker Loses by Default—Norman Baker did not appear at a hearing before the Federal Communications Commission at Washington D. C., February 14, and his application for a permit to open a new broadcasting station in Muscatine was denied. Baker formerly operated Station KTNT at Muscatine, but his permit was canceled because of charges made by the Muscatine County Medical Society. These charges were based on his radio preachments against health measures and all rational treatment of disease, and his insulting accusations against the medical profession. Following his trial, Baker established Station XENT in Nuevo Laredo, Mexico. This station was still operating, February 15.

KANSAS

Bill Introduced—S 454 proposes to exempt from the provisions of the state insurance laws church hospitals which have been in operation ten years or more.

Immunization Campaign—Seventy-seven school districts were visited and 1,400 children were immunized in a campaign against diphtheria recently conducted by the Brown County Medical Society under the auspices of the state board of health. Blanks were sent to parents, and newspapers cooperated in urging all to take advantage of the plan. Completed blanks were plotted on a map according to school districts, in attempt

was made to divide applicants evenly among physicians, and central points were selected for twelve districts with each physician as far as possible in charge of a district within his locality. Toxoid was furnished without cost by the state board of health.

MAINE

Society News—Dr Carl W. Ruhlin addressed the Portland Medical Club, January 2, on "Orthopedic Aspect of Arthritis." Dr Harold V. Bickmore discussed diseases of the gallbladder before the club recently. A paper on tachycardia was presented before the York County Medical Society in Kennebunk, January 9, by Dr Eugene H. Drake, Portland.

MARYLAND

Bill Passed—S 211 has passed the senate, proposing to authorize corporations to organize under the corporation laws of the state for the purpose of operating a nonprofit hospital service plan.

Bill Introduced—H 321 proposes to authorize the sexual sterilization of any inmate of a state institution whenever the superintendent or managing director of the institution is of the opinion that "it is for the best interest of the patients and of society" that he be sexually sterilized.

Anniversary Meeting—The Mental Hygiene Society of Maryland observed its twentieth anniversary at a dinner meeting, February 14. The twenty-fifth anniversary of the mental hygiene movement was also commemorated by the society on this occasion, as it has been by several societies throughout the country in the past several months. The national organization held its celebration, Nov 14, 1934, in New York. Guest speakers on the Baltimore program included Mr Clifford W. Beers, founder of the national movement, and Dr Clarence M. Hincks, general director of the National Committee for Mental Hygiene, both of New York.

MASSACHUSETTS

Shattuck Lecture—Dr William E. Gallie, professor of surgery, University of Toronto Faculty of Medicine, Toronto, Canada, will deliver the Shattuck Lecture at the annual meeting of the Massachusetts Medical Society, June 3, on "Sprains and Dislocations."

Lectures on Mental Hygiene—The state division of university extension and the Massachusetts Society for Mental Hygiene are sponsoring a course of eight lectures on "The Mental Hygiene of Adolescence" at the Calvin Coolidge School, Melrose. The following speakers are participating in the series, which began February 6: Dr Clarence A. Bonner, superintendent of the Danvers State Hospital, Hathorne; Dr Henry B. Elkind, medical director, Massachusetts Society for Mental Hygiene, and Miss Bernice M. Henderson.

Society News—Dr John A. Hartwell, New York, spoke before the Harvard Medical Society February 26, in Boston, his subject was "Your Profession and Society." Dr James W. White, New York, presented a paper before the New England Ophthalmological Society in Boston, February 19, on "Diagnosis and Treatment of Vertical Strabismus." At a meeting of the New England Physical Therapy Society, February 20, Dr Frederick W. O'Brien, Boston, discussed "The Present Status of Radium and X-Rays in the Treatment of Malignant Disease." Speakers before the Massachusetts Psychiatric Society in Boston, February 27, were Drs Salomon Gagnon, Danvers, on "Review of the Problems of Bacillary Dysentery," Leo Maletz, Danvers, "Sodium Fluoride Poisoning," and Paul E. Tivnan, Salem, "Paget's Disease." Dr Herbert L. C. Johnson, Boston, discussed "The Use of Amniotic Fluid in Abdominal Surgery" before the Norfolk District Medical Society, February 26.

MICHIGAN

Dr Stoddard Celebrates One Hundredth Birthday—Dr John Parker Stoddard, Muskegon, was entertained at dinner by the Muskegon County Medical Society, February 22, in celebration of his one hundredth birthday. Dr Stoddard is the oldest living alumnus of the University of Michigan and is said to be the oldest living graduate of Bellevue Hospital Medical College. Speakers included representatives of the University of Michigan and Albion College. Dr Stoddard received a congratulatory telegram from President Roosevelt. About 200 persons attended the dinner. Dr Harold F. Closs, president of the medical society, presided.

Society News—Dr William D. Fullerton, Cleveland, addressed the Wayne County Medical Society and the Detroit Obstetrical and Gynecological Society, February 4, on "Carcinoma of the Uterus, Its Early Diagnosis and Treatment." The Detroit branch of the American Urological Association presented a symposium on hematuria before the Wayne County Medical Society, January 21, speakers, all from Detroit, were Drs Robert A. MacArthur, George C. Burr, Robert M. Cothran, Edward George Olsen, Harold L. Morris and Charles Stuart Wilson. The Oakland County Medical Society met at the Oakland County Tuberculosis Sanatorium, Pontiac, February 20, a clinical demonstration in epidemiology constituted the afternoon program, and Dr George A. Sherman and the staff discussed "Factors in Diagnosis and Treatment of Tuberculosis" in the evening. Dr George W. Hall, Chicago, discussed the "Newer Things in Neurology" before the Calhoun County Medical Society, February 5.

MINNESOTA

Society News—At a meeting of the Minneapolis Surgical Society, February 7, Dr Emil Goetsch, Brooklyn, spoke on "Criteria of Operability for Thyroidectomy."

Bills Introduced—H 579 proposes to amend the law relating to the care, treatment and hospitalization of indigents by permitting the county board of any county in which there is located a hospital designated as a class A hospital by the American College of Surgeons to contract with such hospital to care for and treat indigent residents of the county. H 865 proposes to prohibit the employment of public school teachers, clerks or janitors unless they present certificates from licensed physicians that they are free from tuberculosis in an active form. S 671 proposes to prohibit any public health nurse, public school nurse or employee of a public school or public school board from using his position (1) to promote the business of any particular physician or other practitioner of the healing art or (2) in discrimination for or against any particular school of the healing art.

MISSOURI

Personal—Dr James R. Bunch has been appointed acting superintendent of state hospital number 2, St. Joseph. Dr John O'Connell, Overland, was presented with a loving cup by the St. Louis County Medical Society on his retirement as president, January 9. Dr Fred W. Bailey, St. Louis, has been appointed a member of the Missouri State Board of Health to succeed Dr Emmett P. North, St. Louis. Dr Hyman I. Spector, St. Louis, tuberculosis controller of St. Louis, has been named assistant health commissioner, and Dr James L. Mudd has been appointed to succeed him in the former office. Dr Edwin L. Sheahan, Clayton, has been appointed superintendent of the St. Louis County Hospital, Clayton.

MONTANA

Bill Enacted—H 66 has become a law, requiring both parties to a prospective marriage as a condition precedent to their right to receive a license to wed, to present a physician's certificate that they are free from venereal disease and from tuberculosis in an infectious stage, and that neither of them has been adjudged in a court of competent jurisdiction to be an idiot, an imbecile or of unsound mind.

NEBRASKA

Society News—Speakers at a meeting of the Southwestern Nebraska Medical Society, McCook, January 10, were the following Lincoln physicians: Drs Earl V. Wiedman, on acute conditions in the abdomen in children, Roy H. Whitham, peritonitis and Miles J. Breuer, treatment of arthritis. Dr Nymphus F. Hicken, Omaha, discussed goiter before the Otoe County Medical Society, Nebraska City, January 7. Drs George E. Robertson and Leon S. McGoogan, Omaha, addressed the Madison-Six Counties Medical Society, Norfolk, January 22, on vitamins and minerals in pregnancy.

NEW HAMPSHIRE

Meeting on Economic Problems—A special meeting of physicians, state officials and members of the legislature, sponsored by the New Hampshire Medical Society, was held in Concord, Dec. 13, 1934, to discuss administration of medical relief and sickness insurance. A report on sickness and hospital insurance was presented by Dr Carleton R. Metcalf, Concord, secretary of the state society and James A. Hamilton Hanover, chairman of the State Hospital Superintendents' Club.

NEW YORK

Personal—Dr John A Carswell, Scarsdale, tuberculosis clinician on the staff of the Westchester County department of health, has been provisionally appointed to the staff of the division of tuberculosis in the state department of health, Albany. He has been stationed at the New York State Hospital for Incipient Tuberculosis, Ray Brook, to organize a chest clinic service in the Adirondack district as an outpatient activity. The area to be served includes Franklin, Clinton, Essex and Hamilton counties.—Albert F Blakeslee DSc, acting director of the department of genetics of the Carnegie Institution of Washington at Cold Spring Harbor, has been made a corresponding member of the Academy of Sciences of the Institute of France, *Science* reports.

Bills Introduced—S 1414 and A 1861, to amend the laws relating to the practice of chiropody propose to designate the practice of chiropody as the practice of podiatry and to create an independent board of podiatry examiners. Under the present law, apparently, chiropodists are licensed by the board of medical examiners. A 1883 to supplement the workmen's compensation act proposes to make compensable any disease of the lungs or respiratory tract resulting from the inhalation of dust in any form of (1) mining quarrying and/or dressing of stone, (2) manufacture of refractory materials and abrasives, (3) rock-drilling, sand and/or steel grit blasting, (4) porcelain-enameling, (5) metal grinding and/or polishing (6) lens grinding and/or polishing, (7) pottery manufacture (8) glass-making, (9) foundry work or (10) any occupation involving the preparation or manufacture of asbestos or of articles containing asbestos. A 1863 proposes to prohibit any experiment or investigation to be made on a living dog.

New York City

Sixth Harvey Lecture—The sixth of the present series of lectures presented by the Harvey Society will be given by Dr Gleb V Anrep, professor of physiology, Egyptian University Faculty of Medicine, Cairo, at the New York Academy of Medicine, March 21. His subject will be "The Relation of the Circulation in Voluntary and Plain Muscle to Activity."

Skin and Cancer Unit Opened—Consolidation of the Stuyvesant Square Hospital with New York Post-Graduate Medical School and Hospital was effected with the opening, January 21, of a new skin and cancer unit representing the combined outpatient services of the departments of dermatology and syphilology of the affiliated institutions. The building of the Stuyvesant Square Hospital, formerly known as the New York Skin and Cancer Hospital, has been completely remodeled for the outpatient service all bed patients having been transferred to the Post-Graduate Hospital. It has its own administrative offices, social service, pharmacy laboratories, physical therapy equipment and other facilities. Approximately 1,200 mg of radium owned by the unit has been transferred to the department of radiology of Post-Graduate Hospital. Radium work in the new clinic being limited to cancer and other lesions of the skin. Dr George Miller MacKee, professor of dermatology and syphilology, Columbia University College of Physicians and Surgeons, and head of the department of dermatology at New York Post Graduate Medical School, is director of the new clinic. Dr Carl Eggers is in charge of cancer surgery in the new unit and has been appointed professor of clinical surgery at Columbia. Chiefs of clinics are Drs Charles Mallory Williams, Isadore Rosen, John Frank Fraser and Fred Wise.

NORTH CAROLINA

Physicians in Legislature—Three physicians are serving in the present state legislature. Dr John T Burrus, High Point, is chairman of the senate committee on health. Dr Ransom L Carr, Rosehill, chairman of the house of representatives committee on health, and Dr Charles A Peterson, Spruce Pine, member of the house committee.

Bills Introduced—S 231 proposes to exempt from taxation all general hospitals operating approved training schools for nurses. S 258, to amend the laws authorizing the sexual sterilization of certain socially inadequate persons, whether inmates of state institutions or not proposes that the sterilization operation authorized by the law shall be vasectomy in the case of males and salpingectomy in the case of females, or any medical or surgical method of sterilization which does not include the removal of any sound organ of the body. H 539 proposes to repeal the law requiring a male applicant for a marriage license either to sign an affidavit that he is free from venereal disease and active tuberculosis or to present a certificate from a licensed physician to that effect.

OHIO

Personal—Dr Milton R Kukuk, Toledo, has been appointed health commissioner of Lucas County to succeed the late Dr Fred F Devore.—Dr Richard S Austin was recently elected president of the Public Health Federation of Cincinnati.—Dr Clarence E Northrup, McConnelsville, has been appointed health officer of Morgan County, succeeding Dr Arnold O Abraham, who removed to Niles, Mich.—Dr Harry G Southard, Marysville, retiring state health officer, has been appointed a member of the state public health council succeeding the late Dr Charles O Probst.—Dr William H Hawley, College Corner, was guest of honor at a dinner given by members of the Union Medical Association January 10, in celebration of his fiftieth anniversary in the practice of medicine, at the Hotel Anthony Wayne, Hamilton. Dr William L Porter, College Corner, was toastmaster.—Dr Wade MacMillan, for seventeen years medical director at Miami University Oxford, has announced his retirement, effective at the end of the year.

Bills Introduced—S 137, to amend the medical practice act proposes to require an applicant for a license to practice medicine to have received prior to his admission to medical school either a degree from a reputable college or to have completed satisfactorily at least two full college years in an approved college in premedical subjects. S 145 proposes to create an independent board of chiropractic examiners and to regulate the practice of chiropractic. Chiropractic is defined as "the art and science of locating and the procedure preparatory to adjusting by hand of the subluxations of the articulations of the human spinal column which is deemed to be the twenty-four movable vertebrae including the sacrum and coccyx, and adjacent tissues for the purpose of removing any interference with nerve transmission but it shall not include major surgery nor the administration or prescription of any drug or medicine included in materia medica." H 221 proposes that the provisions of the medical practice act shall not apply to any persons who in the practice of the religious tenets of their church confine their ministrations to the sick or afflicted to prayer and spiritual means and without the use of material medicine or material means or manipulations.

OKLAHOMA

Bill Introduced—S 62 proposes to accord to physicians nurses and hospitals treating persons injured through the negligence of others liens on all rights of action claims, judgments compromises or settlements accruing to the injured persons by reason of their injuries.

New State Health Officer—Dr Charles M Pearce health officer of McAlester has been appointed state health officer to succeed Dr George N Bilby. Dr Pearce is a native of Alabama and a graduate of Birmingham Medical College 1915. He was one of four candidates for the position recommended by the Oklahoma State Medical Association newspapers reported.

OREGON

Bills Enacted—The following bills have become laws. H 180 limiting the distribution of appliances drugs and medicinal preparations intended or having special utility for the prevention of conception and/or venereal diseases, to licensed physicians and to persons licensed to do so by the state board of pharmacy, H 107 repealing the laws regulating the possession and distribution of narcotic drugs and enacting a bill which, although denominated as the "uniform narcotic drug act," deviates from the model act in that it omits provisions intended to limit the gross quantity of a habit-forming drug a person can buy in exempt preparations within a period of forty-eight hours. H 208, prohibiting the distribution of amytal, luminal, veronal, barbital, acid diethylbarbituric, or any preparation or compound containing any of the foregoing substances, except on the prescription of a licensed physician, dentist or veterinary surgeon.

PENNSYLVANIA

Bills Introduced—S 393, to supplement the workmen's compensation act proposes to permit the department of labor and industry, the employer, or the claimant to require an autopsy on the body of a workman dying following industrial injuries. H 1136, to amend the medical practice act, proposes to authorize the bureau of medical education and licensure to revoke or suspend the license of any practitioner who has acted as an adjuster of claim or claims arising out of personal injuries or who has negotiated for the settlement of such claim or claims where such claims do not involve injuries to himself or his or her family. S 417 proposes to create a board of naturopathic education and licensure and to regulate the

practice of naturopathy, which the bill defines as "a philosophy of healing embodying within itself a complete system of therapeutics, basing its treatment of all physiological dysfunctions and abnormal conditions of the body on the Natural Laws governing the body and maintaining life. This system includes the correlation of part with part anatomically, physiologically, psychologically and chemically and does not use drugs or surgery in any manner or form." H 1081 proposes to authorize a licensed optometrist to issue any certificate of ocular or visual efficiency required by any law.

State Society Dedicates New Headquarters—A new building for the headquarters and offices of the Medical Society of the State of Pennsylvania was recently dedicated in Harrisburg. Dr. Edgar S. Buyers, Norristown, chairman of the board of trustees, presided. Mr. Edwin Greene, representing the architects, presented the keys to Dr. Augustus S. Kech, Altoona, chairman of the building committee, who told the history of the movement that culminated in the remodeling of a building bought in 1923. Dr. Kech in turn presented the building and Dr. Moses Behrend, Philadelphia, president, accepted it for the state society. The front of the three story

New Home of the Medical Society of the
State of Pennsylvania

building has been reconstructed of Indiana limestone to conform with public buildings of the state capital and decorated with carved stone and bronze. The first floor has the society's offices and a lobby, on the second and third are apartments from which the society derives an income. A new two story annex has been built providing one large and two small committee rooms, a library and a modern vault for archives. Other speakers were Governor Pinchot, Drs. Arthur W. Booth, Elmira, N. Y., for the Board of Trustees of the American Medical Association; Theodore B. Appel, Harrisburg, for the state department of health; Edward B. Heckel, Pittsburgh, former chairman, Board of Trustees, American Medical Association; and Mr. William M. Demson for the state department of education. A portrait of Dr. Cyrus Lee Stevens, Athens, secretary of the state medical society from 1896 to 1918, editor of the *Pennsylvania Medical Journal* from 1904 to 1920, and president of the society in 1919 was presented to the society by the Bradford County Medical Society. Dr. Stanley D. Conklin, Sayre, made the presentation address. At present the society plans to establish a package library service similar to that of the American Medical Association, rather than to accumulate bound volumes. Three state societies now have this service: Texas, Indiana and Wisconsin.

SOUTH CAROLINA

Bill Introduced—H 422 proposes to accord to hospitals, nurses and physicians, treating persons injured through the negligence of other persons, liens on all settlements or compromises accruing to the injured persons by reason of their injuries.

TENNESSEE

Bill Introduced—H 458, to amend the medical practice act, proposes (1) to provide that members of the board of medical examiners shall be appointed by the governor from a list of names submitted by the Tennessee State Medical Association, and (2) that no license shall be revoked until the licensee has been notified in writing of the charges against him and has been given an opportunity for a full and complete hearing, with the right to be represented by counsel.

University News—Dr. Gunnar Nystrom, professor of surgery, University of Upsala, Sweden, is in residence at Vanderbilt University School of Medicine as Flexner lecturer during February and March. Dr. Morris Fishbein, Chicago, editor of *THE JOURNAL*, gave a public address at the university, February 12, on "Social Aspects of Medicine," and Dr. Maurice Brodie, New York, addressed medical students on poliomyelitis immunization—Kenneth S. Rice, Ph.D., formerly acting head of the department of physiology at the University of Maine, has been appointed to the staff of the department of physiology at the University of Tennessee College of Medicine, Memphis.

TEXAS

Dallas Clinical Conference—The Dallas Southern Clinical Society will present its seventh annual spring conference, March 18-22, with headquarters at the Baker Hotel. Each morning up to Friday there will be a general assembly with addresses by guest speakers, followed by lecture courses given by Dallas physicians. Conferences will be held at luncheons, and afternoons will be given over to clinics at the Baker Hotel, conducted by the guests. Wednesday afternoon there will also be operative clinics at Baylor, St. Paul's and Medical Arts hospitals and all day Friday will be devoted to hospital clinics. Guest speakers and their subjects for the general assemblies will be as follows:

Dr. Elexious T. Bell, Minneapolis: Minn. Relation of Hypertension to Kidney Disease.
Dr. Harry L. Brum, Denver: Recent Studies in the Treatment of Streptococcal Infection by Means of Specific Immune Serums.
Dr. Henry L. Bockus, Philadelphia: So Called Chronic Nonspecific Ulcerative Colitis.
Meyer Bodansky, Ph.D., Galveston: Applications of Chemical Pathology to Clinical Medicine.
Dr. Franklin G. Ebaugh, Denver: Psychotherapy in General Practice of Medicine.
Dr. Harry S. Gradle, Chicago: Systemic Causes of Ocular Diseases.
Dr. Alexis F. Hartmann, St. Louis: Diabetes Mellitus in Infants and Children.
Dr. Jennings C. Lutzenberg, Minneapolis: Ectopic Pregnancy.
Dr. William E. Lower, Cleveland: Problems of Kidney and Ureteral Calculi.
Dr. Douglas Quick, New York: Radiation and Surgery in Cancer Therapy.
Dr. Wallman Walters, Rochester: Minn. Surgical Treatment of Obstructing Lesions of the Biliary Tract.
Dr. Fred Wise, New York: Dermatophytosis of the Feet and Dermatophytids.

In addition, Dr. H. Earle Conwell, Birmingham, Ala., will conduct two clinics on fractures and Dr. Louis Haiman, Baltimore, will conduct clinics on tuberculosis, leukemia and Hodgkin's disease and will participate in a symposium on heart failure. Monday evening, March 18, there will be a meeting open to the public, Tuesday, symposiums on malignant disease of the head and neck and acute intestinal obstruction. Wednesday the symposium on heart failure. Thursday the annual dinner and Friday, a clinic on syphilis at Baylor Hospital. Dr. Curtice Rosser is president of the society, and Dr. David W. Carter, Jr., director of clinics.

UTAH

Bills Introduced—H 217 and H 220 propose to repeal the laws regulating the possession, sale or distribution of narcotic drugs. H 211 proposes to repeal the laws regulating the sale, distribution and possession of narcotic drugs and to enact what apparently is the uniform narcotic drug act.

Annual Registration Due April 1—All practitioners of medicine and surgery licensed to practice in Utah are required to register annually on or before April 1, with the department of registration, and to pay a fee of \$3. If a licensee fails to reregister within from ninety days to six months after April 1, his license can be revoked and will be reinstated thereafter only on his paying the delinquent registration fees and an additional year's fee as a penalty.

VERMONT

Bills Introduced—S 61 proposes to prohibit the sale, distribution or possession of cigarettes, cigars or tobacco or other commodities intended for smoking, containing cannabis indica. H 254 proposes to prohibit any person, other than a licensed physician or a licensed dentist, to use the title "doctor" or the abbreviation "Dr" in connection with his name on any sign, advertisement or "professional card, unless the type of service rendered by him is also designated on such advertisement or "professional" card.

WASHINGTON

Bills Introduced—S 290 proposes to permit "any professional or vocational group of persons required by law to pay a license fee or pass examination tests to form an association with quasi governmental powers. Such association, when organized, is to exercise the powers now exercised by the director of licenses with respect to examining applicants for licenses, hearing grievances against any member and enforcing the law. H Joint Memorial No 30 proposes to petition the United States Congress to pass a law authorizing the deportation of aliens convicted of violating any state narcotic drug act. H 640 proposes to make it unlawful for any person firm or corporation to operate a dental office unless said person shall be a duly licensed dentist within the state of Washington." It shall be unlawful for any person, firm or corporation operating or managing a dental office in the state of Washington to employ any person as a dentist or a dental assistant unless said person is a duly licensed dentist.

WEST VIRGINIA

Society News—Dr Russell C Bond Wheeling addressed the Marshall County Medical Society, Moundsville, January 15 on "Scarlet Fever, Measles and Whooping Cough."—Dr Hugh G Thompson, Charleston addressed the Fayette County Medical Society Oak Hill, January 7, on "Surgical Consideration of Diabetes."—Mr James W Harris Jr, former secretary to Governor Kump, has been appointed executive secretary of the Hospital Association of West Virginia, with headquarters in Charleston.

WISCONSIN

Society News—Drs Richard H Jaffe Chicago, and Francis D Murphy addressed the Medical Society of Milwaukee County, January 11, on 'Kidney and Cardiovascular Diseases and "Nephritis," respectively. The first graduate course of 1935 began January 21, with Dr Joseph L Miller Chicago as the speaker. At the annual meeting of the society Dec 14 1934, Dr Austin A Hayden, Chicago, spoke on "The Institution of American Medicine" and Mr J George Crownhart, executive secretary, State Medical Society of Wisconsin, on 'Medical Legislation.

Children Barred from Public Places in Scarlet Fever Fight—Dr John P Koehler, health commissioner of Milwaukee, has ordered schools, theaters, churches and other public places to bar all children under 7 years old. The commissioner's action, which was taken February 19 with the approval of the city council, is an effort to curb the epidemic of scarlet fever that has been prevalent since September. There were more than 1,500 cases in the city on that date. Plans have been made by the health department to collect blood from convalescent and recovered patients and to prepare a supply of serum for use in the epidemic. A special laboratory has been arranged at the Columbia Hospital for preparation of the serum, the gift of a Milwaukee citizen whose child was benefited by the use of serum. The order isolating young children meant the exclusion from schools of 20,000, closing of kindergartens and almost total closing of first grades.

Bills Introduced—S 190 proposes to amend the law requiring all male applicants for licenses to marry to present a physician's certificate showing that they are free from venereal disease by requiring such certificates of both parties to proposed marriages. A 297 proposes to create an interim committee on the cost of medical care, to consist of two senators and three assemblymen. The committee is to investigate the general subject of the cost of medical care and the ways and means of lightening the burden thereof. A 403, to amend the workmen's compensation act, apparently proposes to permit an injured employee to elect to receive chiropractic treatment for his industrial injuries. The bill proposes, however, that the exercise by the injured workman of his right to receive Christian science or chiropractic treatments is not to relieve him from the requirement of submitting to and following such competent and reasonable surgical treatment as may be required.

WYOMING

Annual Registration Due April 1—All practitioners of medicine and surgery licensed to practice in Wyoming are required by law to register on or before April 1, with the secretary of the board of medical examiners, and to pay a fee of \$2.50. If a licensee fails to pay the fee within three months after April 1, his license can be annulled, and if annulled it will be restored to him only on his paying the stated fee, plus \$5 as a penalty.

GENERAL

Examining Boards—The Advisory Board for Medical Specialties is now receiving applications from special examining boards in the process of organization for official approval and representation in this board. Information on the form for these applications may be obtained from the secretary, Dr Paul Titus, 1015 Highland Building, Pittsburgh, Pa. Action on the applications will be taken at the annual meeting of the advisory board at the Hotel Traymore, Atlantic City, June 9.

Dr Atwater Named Executive Secretary of Public Health Association—Dr Reginald M Atwater for eight years health commissioner of Cattaraugus County, New York has been appointed executive secretary of the American Public Health Association, effective March 15. Dr Atwater graduated from Harvard Medical School in 1918 and took the degree of doctor of public health at Johns Hopkins University in 1921. Later he was appointed associate professor of hygiene in the Hunan-Yale College of Medicine in Changsha, China, from which position he returned in 1925 to teach in the Harvard School of Public Health.

Special Board Examination—An examination of candidates for the certificate of the American Board of Psychiatry and Neurology in neurology, psychiatry or both will be held in Philadelphia, June 7-8, preceding the annual session of the American Medical Association in Atlantic City. It will include examination of patients, with reports on and discussion of the observations, June 7, oral and written examinations in neuro-anatomy, neurophysiology, psychobiology, psychopathology, neuropathology and the interpretation of roentgenograms, June 8. Applications must be filed not later than April 8. Blanks and further information may be obtained from Dr Walter Freeman, 1726 Eye Street, Washington, D C.

Medical Bills in Congress—*Changes in Status* S 1850 has been reported to the Senate, proposing to amend an act entitled "An Act to recognize the high public service rendered by Major Walter Reed and those associated with him in the discovery of the cause and means of transmission of yellow fever," by including Roger P Ames among those honored by the act. H R 2827, the Lundeen social insurance bill, has been voted on favorably by the House Committee on Labor and will be shortly reported to the House. The bill proposes, among other things, to direct the Secretary of Labor to establish social insurance "for the purpose of providing compensation for all workers and farmers who are unable to work because of sickness, old age, maternity, industrial injury, or any other disability." **Bills Introduced** H R 6145, introduced by Representative Dempsey, New Mexico, proposes to prohibit the shipment and transportation in interstate or foreign commerce of cannabis and its derivatives and compounds, except when shipped or transported for medical and legitimate uses by the producer or manufacturer thereof or dealer therein to licensed physicians, surgeons, dentists, pharmacists, druggists and veterinarians, under such rules and regulations as shall be prescribed by the Commissioner of Narcotics.

CANADA

Cancer Program in Ontario—Dr James A Faulkner, newly appointed minister of health for Ontario, has appointed a new cancer commission for the province to continue a cancer program begun several years ago. Three clinics have already been established in Toronto, Kingston and London, with an expenditure of \$300,000 on radium. A subcommittee of the commission will make a study of the distribution of radium with regard to population, techniques in vogue and methods of application under the chairmanship of Dr Oskar Klotz, Toronto. Besides Drs Faulkner and Klotz, members of the new commission are Drs William J Bell, John W S McCullough, John D Leith, Gordon E Richards, John G Fitzgerald, William E Gallie, George E Wilson and Duncan A L Graham, all of Toronto, Prof E F Burton, professor of physics at the University of Toronto. Drs William A Jones, Frederick Etherington and Walter T Connell, all of Kingston. Robert K. Paterson, Ottawa. William J Cook, Sudbury and Frederick J H Campbell, London.

Serious Criticism of the Treatment of Fractures The Teaching of Sir Robert Jones Already Forgotten

In July 1933 the British Medical Association appointed a committee, consisting largely of orthopedic surgeons, to report on the treatment of fractures and associated injuries of the limbs. The report, which has just been published, is a serious criticism of the current treatment, both in private and in hospital practice. There has been a growing feeling among those who have studied the late results that these injuries do not receive the attention they deserve and that great improvement could be brought about by better organization. Comparison of the statistics of the results obtained in organized clinics and of those obtained outside them show a glaring contrast. Thus in 432 adult cases of Colles's fracture treated in organized clinics the average disability period was seven weeks and the number of cases of permanent incapacity was two, while for thirty-eight cases not treated in these clinics the average disability period was twenty-nine weeks and the number of cases of permanent incapacity nine. In forty-five cases of fracture of the shaft of the femur the corresponding figures were twenty-six weeks average disability and one permanent incapacity, against thirty-one cases with sixty weeks' average disability and nineteen permanent incapacities. When the figures for the common fractures (the two mentioned, scaphoid of wrist, clavicle, patella, tibia and fibula, and ankle) were taken together it was found that whereas permanent incapacity occurred in only 1 per cent of cases treated in organized clinics it occurred in no less than 37 per cent of cases not so treated. Moreover, the duration of incapacity was thrice as great in the latter group. During the war, great advances were made in the treatment of fractures under the inspiring leadership of Sir Robert Jones. His recognition of the importance of segregation under one control and of methodical and continuous treatment resulted in extension over a wide area of principles that had been successfully applied on only a small scale. Unfortunately, his fine organization has largely disappeared and the treatment in the majority of hospitals has not materially advanced. In only a few centers is there any organization superior to that which existed twenty years ago.

INADEQUATE ORGANIZATION OF FRACTURE SERVICES

The committee has investigated the fracture services of the large hospitals and found that in the majority there is no efficient organization. The care of the fractures often devolves on the house surgeon, who lacks the knowledge and experience necessary for adequate treatment. On leaving the ward the patient is referred to the massage department, in charge of an officer who has taken no part in the previous treatment. Union of the fracture thus means a complete break in the continuity of treatment.

IMPERFECT SURGICAL TREATMENT

In a high proportion of cases of delayed recovery the fracture was never completely reduced. This was due not simply to inadequate manipulation but to neglect to determine whether or not the manipulation was successful. Failure to use post-reduction x-ray control was frequently responsible. In other cases the important factor was absence of daily supervision of fractures in their early stages, and weeks elapsed before malposition was recognized, so that perfect manipulative reduction was no longer possible. In a smaller proportion of cases, dis-

ability was due to recurrence of deformity that had been corrected. Failure to use the best method of immobilization, to control and check progress by roentgen examination and to maintain immobilization sufficiently long, owing to fear of joint stiffness, were responsible for other cases. Neglect of early active mobilization of uninjured joints accounted for prolonged disability in a large number of cases. Joints were allowed to stiffen unnecessarily, and massage and passive movements were relied on to cure what should have been prevented by active exercise. Even when joint stiffness was inevitable, recovery was frequently delayed by adoption of passive methods to the exclusion of active exercise. Stiff joints became stiffer as the result of injudicious stretching and the belief that massage alone will cure muscle wasting, and recurring edema was responsible for many months of delay.

RECOMMENDATIONS

In the opinion of the committee, the essential conditions of an organized fracture service are segregation of cases, continuity of treatment, after-care, and unity of control. Every hospital should segregate its fracture cases and establish one and only one, organization. Only thus can the staff become sufficiently highly trained and experienced in the technic of modern methods. But such segregation should not exclude any member of the hospital staff interested in fracture treatment. Coordination of the successive stages of treatment is also essential. The patient should not be transferred at a critical stage of treatment from one department to another, or from the care of the surgeon responsible for the initial treatment to one who has no knowledge of or responsibility for it. After care in the form of active exercises directed to complete restoration of function is essential and is often neglected. It should be directed to the performance of tasks and not consist of massage and electrical stimulation, which have been largely misapplied in the treatment of fractures, and injudicious stretching of joints has actually been done. Massage staffs should concentrate on securing the active cooperation of the patient and teaching him to undertake his own remedial exercises. Finally, these measures achieve their greatest success only under unity of control. All stages must be supervised by one expert. In the smaller hospitals one member of the staff should be selected to do the whole of this work.

Memorial to Florence Nightingale

The National Florence Nightingale Memorial Committee of Great Britain is appealing for funds to raise a living memorial to Florence Nightingale to carry on and extend her great work. Already twenty countries have formed or are forming national committees for this purpose. The memorial, by the enthusiastic agreement of the nurses of all nations, will take the form of endowment in London of postgraduate training in public health nursing and of teaching and administration in schools of nursing. Such courses are already in operation, having been established after the war by the League of Red Cross Societies, with the collaboration of Bedford College for Women and the College of Nursing. Scholarships have been financed by the league, which has now exhausted the money available, and by the efforts of nurses federated in the International Council of Nurses. Some 220 nurses from forty-three countries have completed their training and returned to their home countries to fill positions of importance. The Memorial Committee considers that the standardization of nursing throughout the world is of supreme importance, and hardly less the opportunity given to representative women of all nations to meet in social intercourse and study. It is apt to be forgotten that Florence Nightingale reformed nursing in all its branches, whether civil or military. She revolutionized hospitals and hospital administration, so that, from being in

many cases pesthouses of disease, they became the hygienic and sanitary places known today. The sum required to be raised in Great Britain is \$1,000,000.

The Ill Effects of the Smoke Pall of Manchester

In his report for 1933, Dr D P Sutherland, health officer of Manchester, says that the smoke pall, which is constantly present to a greater or less degree over this district, has several adverse effects. Its presence is recorded in the rapid blackening and deterioration of buildings, it reduces by 50 per cent the actinic value of the sunlight and in winter leads to the formation of fog. Sufferers from tuberculosis have their respiration, already impaired by disease made more difficult by the acute irritation of the impurities in the air. Further inflammation results, resistance is broken down, toxemia increases, and heart failure follows. A correlation between fog and the death rate is shown by statistics. During the fogless period April-September 1933, the average weekly deaths amounted to 127. During the fogless winter weeks the average was 144 but in the winter foggy weeks it was 165. Fogs are associated with an increased death rate from tuberculosis.

"Deformed" Types of Syphilis

A leading authority on syphilis, Professor Gougerot of Paris, contributed an important article in the *Revue générale de clinique et de thérapeutique*, October 20. The classic dogma that syphilis develops in three periods, beginning with the chancre and invading the body slowly by way of the lymphatics and becoming a systemic infection (by way of the blood vessels) at the time of the secondary manifestations, has been rendered obsolete as the result of modern research. Numerous new conceptions of syphilis have completely changed former teachings. The efficient therapeutic agents of the present day, even though they do not always cure syphilis, modify it greatly and the result is that one finds a disease quite different from the schematic notions of preceding generations. If one is not familiar with the forms of syphilis as modified by modern methods of treatment, there is a great risk of errors in diagnosis with resultant serious danger from the social and familial standpoint. Gougerot groups these altered or, as he terms them, "deformed" types of syphilis, as follows:

1 Primary syphilis retarded in its development by inadequate prophylaxis, that is, before appearance of the chancre. Every method of prophylaxis is liable to be unsuccessful in certain cases. In thirteen cases treated with ointment of mild mercurous chloride the chancre developed in five cases in milder form and at periods varying from thirty-nine to sixty-three days after infection. These failures are seen also following the use of other methods of prophylaxis, even after intravenous use of neoarsphenamine. One should be careful not to assure the patient that syphilis in an attenuated form might not appear at a later period, as if no preventive treatment had been given. If one wishes to avoid failure in prophylaxis, arsenical preparations must be given in as strong doses and over as long a period as though the chancre were already present. The patient must be followed clinically and serologic reactions carried out over a period of from two to four years.

2 Syphilis deformed or retarded by inadequate abortive treatment. In these cases the classic secondary manifestations instead of appearing forty days after the chancre, are not observed until after ninety days or even as late as 190 days, as in one of Gougerot's cases, at a period when one felt that the syphilis had been aborted by the treatment given at the time of appearance of the chancre. In some of these "retarded"

cases only a single secondary manifestation may be observed, in the form of a few mucous patches or of a generalized adenopathy. Some spirochetes persist in the vicinity of the chancre and remain latent, only to develop suddenly at some later period and become disseminated in the body.

3 Early tertiary syphilis because of inadequate treatment. As early as 1910 Gougerot called attention to the fact that, when arsenical preparations had been given for an insufficient length of time, tertiary signs in the form of gummas on the skin and mucous membranes, or serious localized destructive lesions of the viscera or along the course of the cranial nerves, would appear at a comparatively early date. There has been much discussion as to whether these were the result of the syphilitic infection or of the toxic action of the arsenic or both. Gougerot is of the latter opinion, especially in regard to nerve lesions, and hence, instead of arsenical preparations which may increase the toxic element, he prefers to use mercuric cyanide or, better still, a bismuth compound. To avoid such early tertiary manifestations, the treatments should not be given over too short a period or in too small doses, and the intervals should not be over a month in duration.

4 Cases that are either resistant to or show recurrences even after arsenic. These patients often present a papulosquamous psoriasis-like eruption, and even though the disease is active the Wassermann reaction is negative.

PERSISTENCE OF POSITIVE WASSERMANN REACTIONS

In connection with the fourth group of Gougerot's deformed syphilis, a recent paper by Tzanck and his associates, read at the Oct 19, 1934, meeting of the Medical Society of the Paris public hospitals is of great interest. These observers base their opinions on the observation of more than 10,000 cases of syphilis at St Anthony's Hospital. They reported fifty-seven cases in which the Wassermann, Hecht and Kahn reactions, made simultaneously, remained positive in spite of treatment given over a period of a minimum of three years. These resistant positive reactions are most frequently observed in cases of visceral syphilis or when there is a complete absence of any manifestation of the disease. There were thirty-two cases treated at regular intervals for at least four years and fifteen others over a period of three years. In none of these resistant seroreaction cases was the patient treated at regular intervals, with multiple preparations and intensively. In the majority the diagnosis of syphilis had been made at the period when a cutaneous eruption or a visceral lesion appeared. In twenty-four of the thirty cases treated for four years, and in eleven of fifteen treated for three years, the positive reactions were discovered during the course of treatment. In the other cases the diagnosis had been made in the primary or secondary period but the treatment had been inadequate. In four persistently positive cases, congenital syphilis had been treated for a long period. After four years of treatment, examination of these persistently positive cases revealed the presence of a visceral syphilis (nervous or aortic) in eleven, mucocutaneous manifestations in five, and nothing in fifteen cases. In all of the forty-seven persistently positive cases, the disease had been inadequately treated in its early stages, no treatment had been given or it was given too late. In not a single case have Tzanck and his associates ever observed a persistence of a positive seroreaction when the treatment had been given early enough and regularly over a sufficiently long period.

Treatment of Migraine

Dr Pagniez, who is well qualified through intensive study, directs attention to the progress that has been made during the last twenty years in the etiology and treatment of migraine. In the *Presse médicale* January 2, he stated that the treatment varies according to the type, he mentions five types:

1 Migraines apparently of digestive origin. A diet that can be easily followed should be given. The only fat allowed is fresh butter. Very good results are obtained in prescribing peptone 0.5 Gm. three quarters of an hour before meals.

2 Migraines of hepatic origin. Here a diet in which all fatty foods are excluded is essential. Regular evacuation of the biliary tract is best attained by ten day treatments with magnesium sulphate and peptone taken before breakfast, followed by the patient lying on his right side for three quarters of an hour, and by the use of the duodenal tube and a 33 per cent magnesium sulphate solution.

3 Migraines of anaphylactic origin. Here the particular food should be looked for the ingestion of which is followed by attacks. Chocolate may be placed at the top of such a list. One should try the well known skin reactions and various diets in which certain foods are omitted, for example milk and eggs or meats or starchy foods. Anaphylaxis due to other causes than foods are rare, but occasionally certain odors, such as tar, will be followed by an attack. The peptones given before meals are especially useful in this type.

4 Migraines of endocrine origin. Here are recognized a thyroid, an ovarian and a hypophyseal type. In the first named in which there is hypothyroidism, the gland extract helps. In cases of ovarian origin there is usually a hypofunction and hence estrogenic preparations or anterior pituitary extract are indicated. In those of hypophyseal origin the posterior lobe preparations are efficacious.

5 Migraines of vascular and sympathetic origin. Small doses of glyceryl trinitrate or the nitrites are best here.

Quite often, migraine presents itself in a less characteristic manner than these types would indicate. These are the so called mixed cases, for which there are a number of causes. For the latter, one must have a number of preparations in mind. These are the barbiturates, the ergotamine tartrate used first by Tzanck and Trautmann several years ago, bromides and the borico-potassic or sodium tartrates. Cases of digestive origin are helped by treatment at Vichy, Vittel or Chatel-Guyon. The remainder of the paper takes up in detail the treatment of the attack itself.

New Regulations Affecting Medical Practice

The executive committee of the Prussian *ärztekammern* (chambers of physicians) held a session at which some important matters were decided. As previously announced, it is planned to create an ethical council of federal physicians, but it is uncertain just when the plan will be consummated.

One question that came before the committee concerned the sale of a medical practice to a successor. According to the code of ethics of German physicians such a sale is absolutely inadmissible, for it is not a question of an actual business that, after the death of the owner, must be sold at as high a price as possible. Only material goods are subject to sale. In any event, it is impossible to make the number of patients the basis of intrinsic value. It has been observed also in many cases in which a sale of a practice was effected that the purchasing physician later sought to have the contract canceled because he felt that the practice had not turned out as represented. That is explained by the fact that a portion of the patients, after the death of the former owner of the practice, transfer their patronage elsewhere with the result that the practice shrinks. The executive committee decided that, before a contract concerning the transfer of a medical practice can be consummated, the consent of the competent chamber of physicians must be secured, whereby also the material possessions of the decedent will be appraised at their proper value.

In the matter of physicians' signs affixed to the house in which a medical practice is carried on, the report brought out that "great confusion prevails, particularly in the large cities," in spite of the fact that definite regulations have been in force for years. In some sections startling incongruities have arisen, while in other sections there is some semblance of order. In spite of former action on the part of medical organizations, the necessary reforms have not been carried out. The medical profession must never in its external manifestations, adopt the methods of industrial plants.

Contrary to former decisions, no medical specialist may in the future designate two branches of medicine in which he is specializing even though he has had special training in two specialties. Likewise, no specialty will be recognized that is not specifically mentioned in the "richtlinien" (medical standards) adopted by the medical profession. The same rules apply to public notices, letter heads and prescription blanks and patients' record cards, which have been issued of late to patients by some of the enterprising physicians and which the patients are expected to bring with them for later consultations, in order that their personal histories may be looked up. Also these record cards must be held strictly within the prescribed limits. Physicians' signs may not bear any statement as to their hospital activities, as to service as director or head of a department, or the like. It was further decided that there is no general need of having physicians' signs illuminated at night.

Another question concerned the seasonal changing of one's place of practice. For some time past, the physicians who are permanently located in watering places have complained that during the summer months a large portion of their practice is taken away from them by the physicians who accept service at health resorts for the summer season. The physicians who are permanently located in the place have but little practice other than during the season, so that they are to a great extent dependent on the summer guests. In view of this fact the seasonal change of one's place of practice has been prohibited.

For the prevention of illegal interruptions of pregnancy, the minister of justice has been requested to establish a special department in the state's attorney's office for the handling of such cases or to declare illegal interruption of pregnancy to be a treasonable act and hence subject to a severe penalty.

For the early recognition of cancerous disease, the possible value of establishing special consultation hours in the polyclinics was discussed. It was decided that, during the coming year every physician must take a course in the diagnosis of cancer, the time and place to be designated by the chamber of physicians having jurisdiction. Great care must however, be taken not to awaken undue fear of cancer among the people.

The Students' Health Service

The goal of the *Studentischer Gesundheitsdienst* is to aid students in the acquisition of health free from hereditary taint and the ability to think and act in keeping with the best traditions of their race. Application of economic measures for the aid of the sick (which were available to a wide extent also under the old régime), prophylactic measures, and elimination of the unfit. Hence, since the beginning of the summer semester of 1934, all students must submit to a physical examination, in which work the bureau of public health of the national-socialist party cooperates. This arrangement, it is asserted, furnishes a guaranty that the examinations will take into account all the questions that are considered important for the selection of future academic leaders. A card index preserves a record of all noteworthy observations. In the future the question of admitting the questionably fit to academic studies will be decided by the results of the compulsory examination. In order that no one may escape being examined, the penalty for such

evasion is exclusion from university studies. The sanitary record card accompanies the student as a "health passport" throughout his whole university career. The last great task, the biologic selection, has not yet been begun. This is regarded, however, as the most important control feature. "The elimination of the unfit is designed to protect the biologically valuable progeny at the universities from the damaging competition of the undesirables." When these important tasks have been more generally applied, it will be necessary to afford this biologically valuable progeny an opportunity to marry and receive an adequate beginning salary. This will necessitate a shortening of professional training in the interest of the people as a whole.

MOSCOW

(From Our Regular Correspondent)

Jan 29 1935

The Histologic Conference

The first All-Russian Histologic Conference was held in Moscow in 1934, with 362 delegates from thirty nine towns. Among them were eighty-eight professors, eighty private assistant tutors, 134 assistants and forty-eight aspirants. Prof. A. V. Nemilov read a paper on the present state of the cellular theory. He considers the cell a certain stage in the development of the organism and thinks that the only true cell in the real sense of the word is the ovum at the moment of impregnation. Roumiantzev spoke about tissue cultures. He analyzed the evolution process in vitro and in vivo and compared the process of growth and differentiation of various tissues.

The report of G. J. Roskin on growth and fission of cells and tissues attracted special attention. He studied the influence of light and medicaments on cells and proposed a theory on the influence of quinine on cells. He finds that after penetrating the cell, quinine accumulates in the granular elements, after which occurrence the granulations do not take a stain. In connection with this phenomenon a disturbance of digestion and of other functions of the organism takes place.

F. M. Makarenko spoke of a new method of tissue transplantation by means of introducing small pieces of tissue with celloidin under muscular fascias. The growth of cells around the celloidin and a further differentiation of the tissues may be observed.

Treatment of Diseases of the Vegetative Nervous System

Dr. R. A. Grot three years ago began treating diseases of the vegetative nervous system by means of diathermy of different regions of the vagus nerve by which method he has healed skin, stomach and leg ulcers. The best results were obtained in the treatment of tabes dorsalis by diathermy of the neck and ischiolumbar regions of the vegetative nervous system. Chronic patients show a reestablishment of the pupillary reaction to light, and the atrophic process in the ocular nerve stops. The observations of Dr. Grot were verified in the institute of Setchenov on 200 patients. This makes it possible to expect that the treatment of trophic disturbances by means of diathermy of corresponding regions of the vagus nerve will permit the treatment of diseases at present considered incurable.

The Moscow State Scientific Medical Library

The Moscow State Scientific Medical Library was founded in 1929 and had then about 35,000 volumes. At present it has more than half a million volumes and 32,000 readers. It supplies with books all the physicians of the Soviet Union. The library selects literature on all medical questions and sends it on request to China, Japan, Argentina, Australia and all the European countries. The "Great Soviet Medical Encyclopedia," which will be completed in a few years (the thirty-first volume

has already appeared), is published under the bibliographic supervision of this library. At present the library is situated in an old house in the center of Moscow, but in the near future there will be erected a special building.

A Method of Vascular Dissection

Dr. Quevedo reported, before a meeting of surgeons in Mexico City last November, the results of his observations on the distribution of the arteries in the kidney by washing the renal and polar arteries, followed by injection of stains of different color into those arteries by the posterior route and destruction of the renal parenchyma by a corrosive substance, which attacks the renal tissue but not the renal arteries. The anatomic specimens obtained by this technique are very clear. Even the most minute arterial ramifications are visible with greater clearness than they are in the best anatomic dissections. He thus found a polar artery in nineteen kidneys of his series of thirty. It was in the upper pole in thirteen kidneys and in the lower pole in six kidneys. He noticed also that the polar artery supplies a large area, sometimes a third or a fourth of the renal parenchyma. This area may become necrosed following an infarction during an operation on the kidney. Dr. Quevedo's study is important to renal surgery and also as a method for the study of the arterial distribution in other organs, for instance in the heart a similar study of the coronary arteries would clarify the picture of such conditions as cardiac infarction and angina pectoris.

Congress of Physicians of the Pan-American Railways

The first Congress of Physicians and Surgeons of the Pan-American Railways will meet, May 5, in Mexico City, as a part of the program of festivities for the opening of the Central Hospital which was built by the Mexican National Railways at a cost of 1,500,000 Mexican pesos (about \$405,000). Physicians and surgeons of all American railroads have been cordially invited to attend. The invitations have been sent both directly from Mexican physicians and through the secretariat of foreign affairs and the consular offices in the United States and the countries of South America, Central America and Canada. The head surgeon of the Mexican National Railways has invited certain physicians to present papers on occupational diseases of workers on railroads and has requested them to send at their earliest convenience a summary of their papers, in order to prepare the program, also a note stating the number of tickets they desire. After the congress the attendants will be taken to the most interesting places in Mexico City and its surroundings.

Marriages

SKOTTOWE BELLINGER FISHBURNE, Columbia, S. C. to Miss Bernice Robertson Pollok of Danville, Va. January 12.

LEON RAPHAEL STATON, Hendersonville, N. C. to Miss Nancy Terrell of Lynchburg, Va., January 12.

AMOS NEILL JOHNSON of Garland, N. C., to Miss Mary Allan of Fort Lauderdale, Fla., February 6.

JOSIAH EDGAR HAYNESWORTH, Buckingham, Va., to Miss Paula Irving of Farmville, January 19.

JOE GIDEON HUFSTEDLER, Knoxville, Tenn., to Miss Boatwright in Memphis, January 26.

WILLIAM T. BARRON JR., Manning, S. C., to Miss Eve Gable of Sumter, Oct. 26, 1934.

FRANK SABISTON to Miss Ethel Anne Roberts, both of Kingston, N. C., January 15.

JOHN CHAMPLIN to Miss Frida Moehl, both of Westerly, R. I., January 30.

Deaths

Franklin H. Martin [†] died of coronary thrombosis while in Phoenix, Ariz., on Thursday, March 7, aged 77 years. His death culminated a career devoted to organizational efforts, particularly in the field of surgery, leading toward the advancement of that specialty in medical science and toward a better understanding by the public of the work of the physician. Only recently Dr. Martin had completed and published his autobiography under the significant title 'The Joy of Living' and also a record of the work of the Council of National Defense—Medical Section—during the World War.

Dr. Martin was born in Verona, Wis., July 13, 1857. Following his education in the public schools and academies of Wisconsin, he received his medical education in Northwestern University Medical School, Chicago, graduating in 1880, and filled an internship in Mercy Hospital until 1881. In 1886 he married Isabelle Hollister, daughter of John Hollister, founder of Northwestern University Medical School. During the same year he became professor of gynecology in the Chicago Polyclinic. In 1880 he undertook organization of the Post-graduate Hospital School of Chicago and from that time continued to devote himself to educational work and to his practice in gynecology. He published a number of monographs in that field, including one on 'Treatment of Fibroid Tumors of the Uterus' in 1897 and 'Treatise on Gynecology' in 1903.

However, his most significant work began with the establishment of *Surgery, Gynecology and Obstetrics* in 1905, to which, in 1913, was added the *International Abstracts of Surgery*. The development of this publication and its relationship to surgical practice led to the formation of the Clinical Congress of Surgeons of North America in 1910 and thereafter the American College of Surgeons in 1913. In this work were associated such leaders in American surgery as Drs. William J. Mayo, A. J. Ochsner, John B. Murphy and George W. Crile. Many of the accomplishments of Dr. Martin for the advancement of surgery depended on the manner in which he was able to secure the whole-hearted cooperation many times at great self-sacrifice, of distinguished leaders in the field of surgery in this country.

During the great war, Dr. Martin was asked by President Woodrow Wilson in October 1916, to head the development of medical participation. He was chairman of the general medical board of the Council of National Defense and a member of the executive committee under which state and county committees of medical men were organized. He was also responsible for the development of the Volunteer Medical Service Corps, in which numbers of American physicians enrolled. During his participation in military activities he was Colonel in the Medical Corps of the United States Army, and with the American Expeditionary Forces for three months.

His position of leadership and the success of his efforts brought to him honors and recognition from many places. Among other decorations were the Companion of the Order of St. Michael and St. George bestowed by King George V of Great Britain, Nov. 13, 1919; the Distinguished Service Medal of the United States Government and the Order of Commander of the Crown of Italy. He received also the LL.D. of Queen's University, Belfast, Ireland of the University of Wales, Cardiff, and the University of Pittsburgh. There was given to him the honorary D.Sc. of Northwestern University and D.P.H. of the Detroit College of Medicine and Surgery.

Not only as a leader in the field of medicine, however, did Dr. Martin serve his fellowmen. He edited *Surgery, Gynecology and Obstetrics* continuously from its foundation to the day of his death. He was director general of the American College of Surgeons from its organization in 1913 to the day of his death. He was president of the American College of Surgeons in 1929, president of the International Association of Gynecologists and Obstetricians in 1919, Trustee of Northwestern University from 1921 to 1931, and a member of boards of trustees and adviser to many other educational, scientific organizations and institutions. He extended the influence of the American College of Surgeons to European and South American countries and, in association with this work, received the honorary fellowship and membership of many of them. He contributed liberally to civic organizations both in Chicago and elsewhere.

Among other activities was the founding and leadership of the Gorgas Memorial Institute of Tropical and Preventive Medicine, a plan of considerable scope proposed with the idea of extending medical knowledge widely to the public and to enlist public support, which seems to have failed to fulfill the scope that its founder conceived for it.

In his leadership of the organizations that he founded and directed, Dr. Martin revealed an imaginative brain, a quick comprehension of public interest, and initiative that was highly alert almost to the day of his death. One found his organization continually creating new committees and new investigative bodies as rapidly as the changing conditions of our civilization indicated their desirability. The development of the motion picture, the rise of industrial medicine, the trend toward social security, and many similar developments were promptly recognized by his organization in the manner that has been mentioned. Dr. Martin was a genial man, a lover of music and of all the arts, and a widely traveled citizen of the world. His commanding appearance, his quick and humorous eye, his alert carriage and the brilliance of his personality brought him recognition and prestige which he more than merited.

Elmer Isaac McKesson [†] Toledo, Ohio, Rush Medical College, Chicago, 1906, past president of the Academy of Medicine of Toledo and Lucas County, the International Anesthesia Research Society, and the Interstate Association of Anesthetists, member of the Associated Anesthetists of the United States and Canada,

aged 53, member of the staff and anesthetist to the Toledo Hospital, St. Vincent's Hospital, Lucas County Hospital, Toledo State Hospital and the Flower Hospital, where he died, February 22.

Archibald Cecil Kane, Oak Park, Ill., Queen's University Faculty of Medicine, Kingston, Ont., Canada, 1920, member of the Illinois State Medical Society, instructor in laryngology, otology and rhinology, University of Illinois College of Medicine, Chicago, served with the British Army during the World War, consulting surgeon to the Municipal Contagious Disease Hospital, Chicago, and formerly on the staff of the Illinois Eye and Ear Infirmary, Chicago, aged 42, died, February 10, of coronary thrombosis.

Daniel Roe Ayres, New York, Columbia University College of Physicians and Surgeons, New York, 1909, assistant professor of gynecology, New York Post-Graduate Medical School of Columbia University, fellow of the American College of Surgeons, at various times on the staffs of the Southside Hospital, Bay Shore, New York, City Hospital and the Post-Graduate Medical School and Hospital, aged 51, died, February 21, of pulmonary and laryngeal tuberculosis.

FRANKLIN H. MARTIN, M.D., 1857-1935

Arthur Hartley, Philadelphia, Hahnemann Medical College and Hospital of Philadelphia, 1898, professor of applied anatomy at his alma mater, fellow of the American College of Surgeons, served during the World War, aged 62, on the staffs of the Delaware County Hospital, Drexel Hill, the Women's Homeopathic Hospital, St Luke's and Children's Hospital and the Hahnemann Hospital, where he died, February 10

Joseph Raymond Burns, Syracuse, N Y, Syracuse University College of Medicine, 1907, member of the Medical Society of the State of New York, associate professor of clinical obstetrics at his alma mater, on the staffs of the University Hospital, Hospital of the Good Shepherd, St Joseph Hospital and the Syracuse General Hospital, aged 48, died January 29, of chronic arteriosclerotic nephritis and myocarditis

Caroline Carle Lawrence, Long Beach, Calif, Woman's Medical College of Pennsylvania, Philadelphia 1894, for many years medical inspector in the public schools of Gary, Ind, formerly a medical missionary, at one time college physician and professor of hygiene at the Elmhurst (N Y) College, aged 65, died, January 30, of a hip fracture received in a fall and of acute nephritis.

Frank M Durham, Columbia, S C, Medical College of the State of South Carolina, Charleston, 1903, member of the South Carolina Medical Association, veteran of the Spanish-American War, aged 59, died, February 1, in the South Carolina Baptist Hospital, of injuries received when struck by an automobile

Thomas Milton De Arman, Miami, Okla, University of Oklahoma School of Medicine, Oklahoma City, 1928, member of the Oklahoma State Medical Association, aged 33, died, January 28, in the Oklahoma General Hospital, Oklahoma City, of complications following pneumonia

Jacob Ziegler Hoffman, Wichita, Kan, University of Pennsylvania Department of Medicine, Philadelphia 1886, past president of the Sedgwick County Medical Society, chief of the medical staff of the Wichita Hospital, aged 72, died, January 28, of coronary thrombosis

Oscar Franklin Blank, Los Angeles, Bellevue Hospital Medical College, New York, 1889, member of the board of St. Luke's Hospital, Bethlehem, Pa, aged 67, died, January 25, in the California Hospital, of bronchopneumonia, following an abdominal operation.

Philip Elwood Stigers, Hancock, Md, Jefferson Medical College of Philadelphia 1887, member of the Medical and Surgical Faculty of Maryland and the West Virginia State Medical Association, aged 70, died suddenly, January 29, of heart disease

Charles A Bevan, West Haven, Conn, Medical-Chirurgical College of Philadelphia, 1887, health officer of West Haven for many years, at one time member of the school board, aged 85, died, January 29, of cerebral hemorrhage

Ernest Lacy Smith, Eastman, Ga, University of Georgia Medical Department, Augusta 1899, member of the Medical Association of Georgia, aged 59, died, January 28, of cerebral hemorrhage while visiting at the State Hospital, Milledgeville

Charles McIlroy Brown, Kansas City, Kan, University Medical College of Kansas City, Mo, 1913, on the staffs of the Bethany and Providence hospitals, aged 46, died, January 13, of acute dilatation of the heart and pulmonary edema

Charles H Teasdale, Crystal Springs, Miss, University of Louisville (Ky) Medical Department, 1884, Civil War veteran, aged 90, was found dead, January 21, as the result of his clothing being ignited from an open fireplace.

Andrew Jackson Hesser, Hollis, N Y, Western Pennsylvania Medical College, Pittsburgh, 1896, veteran of the Spanish-American and World wars, formerly a missionary, aged 67, died, January 22, of heart disease

Edward Tanner, Battle Creek, Neb, University of the City of New York Medical Department, 1879, past president of the Madison County Medical Society, aged 79, died, January 29, of arteriosclerosis and pneumonia

John H Hendrix, Hawkinsville, Ga, Atlanta College of Physicians and Surgeons 1902, formerly mayor of Jasper and member of the board of education, aged 57, died, January 24, of influenza and heart disease

Michael Dugan Spurck, Los Angeles, University of Pennsylvania Department of Medicine, Philadelphia 1904, aged 52, died January 29, in the Queen of the Angels Hospital, of cerebral hemorrhage

Arthur Leonard Jacobson, Seattle, Johns Hopkins University School of Medicine, Baltimore 1921, on the visiting staff of the King County Hospital, aged 39, died, January 28, of heart disease

Pasquale Conca, Providence, R I, Regia Università di Napoli Facoltà di Medicina e Chirurgia, Italy, 1899, on the staff of the Homeopathic Hospital, aged 62, died, January 28, of pneumonia

Lily Victoria Hampton, Portland, Ore, Willamette University Medical Department, Salem, 1889, aged 67, died, January 27, of myocarditis, arteriosclerosis and cerebral hemorrhage.

Philip Israel Levine, Brooklyn, New York, Homeopathic Medical College and Flower Hospital, 1927, aged 31, died, January 18, of a cranial lesion and acute encephalitis

George W Eggleston, Hudson, N Y, National Homeopathic Medical College, Washington, D C, 1895, died, January 30, of hypertrophy of the prostate

George Ash Taylor, New York, University of Maryland School of Medicine, Baltimore, 1890, aged 67, was found dead in bed, Dec 30, 1934, of heart disease

Paul Lawrence, Haughton, La, University of Louisiana Medical Department, New Orleans, 1867, aged 95, died suddenly Nov 3, 1934, of angina pectoris

William Chase Bennett, Toledo, Ohio, Rush Medical College, Chicago, 1893, served during the World War, aged 67, died, January 31, of carcinoma

Joseph Etienne Telephore Dussault, St David de Lévis, Que, Canada, Laval University Faculty of Medicine, Quebec, 1894, aged 63, died, January 1

Lorne De Corsia MacIntosh, Hartland, N B, Canada, McGill University Faculty of Medicine, Montreal, Que., 1904, aged 58, died, Dec 11, 1934

Fred L Duckworth, Monticello, Ark, Chattanooga (Tenn) Medical College, 1905, aged 52, died, January 24, as the result of a cerebral hemorrhage

Christopher Harfield West, Mayne, B C, Canada (licensed in British Columbia in 1923), aged 74, died, January 13, of angina pectoris

Henry Perkins Stockwell, Stanstead, Que, Canada, McGill University Faculty of Medicine, Montreal, 1898, aged 59, died, Dec 29, 1934

Joseph Rainford Warren, New York, McGill University Faculty of Medicine, Montreal, Que., Canada, 1918, aged 51, died, Dec 28, 1934

Tecumseh D S McCall, Caliente, Nev, St. Louis College of Physicians and Surgeons, 1888, aged 68, died, January 5, of uremia

Florence John Halloran, Chatfield, Minn, Rush Medical College, Chicago, 1888, aged 76, died, January 23, in Jackson, of urinary calculi.

Lesco Albert Robinson, Spokane, Wash, Rush Medical College, Chicago, 1896, aged 63, died, January 19, of influenza and heart disease

John A Thompson, McComb, Ohio, Homeopathic Hospital College, Cleveland, 1881, aged 86, died, Dec 28, 1934, of arteriosclerosis

Thomas A Lowery, Fort Worth, Texas, Physio-Medical College of Texas, Dallas, 1906, aged 66, died, January 18, of pneumonia

Thomas Winfield Tuggle, New York, Medical College of Ohio, Cincinnati, 1882, aged 73, died, Nov 12, 1934, of coronary thrombosis

Wilbert A Uhl, Baldwin City, Kan, Fort Wayne (Ind) College of Medicine, 1882, aged 75, died, January 7, of myocarditis

Egbert A D Goldsmith, Seattle, Chicago Homeopathic Medical College, 1903, aged 58, died, January 18, of heart disease.

Laban Theodore Loar, Gary, Ind., Louisville (Ky) Medical College, 1891, aged 74, died, January 16, of bronchopneumonia

Adam E Vrooman, Lindsay, Ont, Canada, Faculty of Medicine of Trinity College, Toronto, 1872, died, January 27

CORRECTION

Dr Garcelon Was Not Officer of American Medical Association—The statement in the obituary notice of Dr Alonzo Marston Garcelon of Lewiston, Maine, in THE JOURNAL, March 2, that he was a Trustee of the American Medical Association, 1883-1901, and in 1901 was elected Vice President, was an error. Dr Alonzo Garcelon of Lewiston, who died in 1906, was an officer of the Association.

Bureau of Investigation**G R BIGLER, QUACK****A Medical Mail-Order Prostate Treatment
Declared Fraudulent**

G R Bigler of Springfield, Ill., is not a physician, chemist or pharmacist, nor does he employ a physician, a chemist or a pharmacist, yet for some time prior to Nov. 21, 1934, this man was engaged in the sale through the mails of a preparation called "Bigler's Guaranteed Prostate Treatment" for the alleged relief and cure of "prostate trouble." On the date mentioned the United States mails were closed to Bigler under his own name as well as under the names "Bigler's Prostate Treatment," "Bigler's Guaranteed Prostate Treatment" and Bigler Company.

As is common in all such cases, Bigler secured business through advertisements placed in periodicals and magazines offering his alleged treatment for sale. A typical advertisement read as follows:

**'PROSTATE SUFFERERS
GET QUICK RELIEF**

and positive results with our inexpensive home treatment. Send for guaranteed trial offer and valuable information free.
BIGLER CO

SPRINGFIELD ILLINOIS

Those who answered such advertisements received a form letter from Bigler in which they were urged to "act at once and get Bigler's Guaranteed Prostate Treatment on our liberal money-back guarantee that you must get satisfactory results and relief." The treatment was said to be different from other "home treatments" and consisted in applying "a positive treatment directly to the prostate." It was said to be "a valuable ointment" that, if given by a physician, "would probably cost ten times as much." The "home treatment" consisted of the ointment and some tablets and three finger cots to be used in applying the ointment. The "treatment" cost \$4.85. When analyzed by the government chemists, the ointment was found to be a simple mixture of petrolatum and wax. The tablets were hexamethylenamine.

The postal authorities, under date of Oct. 18, 1934, notified Bigler and his various-named concerns to show cause by Nov. 12, 1934, why a fraud order should not be issued against them. No one representing Bigler or his companies appeared at Washington on the date set, but a written answer, together with certain documentary evidence, was submitted. The government was able to show, of course, that the so-called Bigler treatment did not "give immediate relief" to persons suffering from "prostate trouble" nor did it remove or assist nature to remove the cause or causes of such disorders. The government also showed that the daily massage of the prostate gland, as recommended by Bigler, might in many cases be harmful. Government experts pointed out, further, that although Bigler was recommending his treatment to all persons suffering from prostate trouble, regardless of their age or the cause of the condition, the treatment, which was the same in all instances, was neither rational nor scientific.

Bigler promised to refund all remittances to those who did not get "satisfactory results" after using the treatment for thirty days. It was shown that, as a matter of fact, he refused to make such refunds in many instances, due to the fact that purchasers had not written him every five days for the purpose of keeping him informed as to any alleged progress. Investigation also disclosed that in some instances, instead of affording relief, the Bigler treatment actually increased the symptoms and caused the user greater pain. In such cases, if the user discontinued the treatment, he was automatically deprived of any opportunity, under the terms of the guarantee, to obtain a refund.

In view of all the facts, Judge Karl A. Crowley, Solicitor for the Post Office Department, declared that, on the evidence, he found Bigler's scheme to be one for obtaining money through the mails by means of false and fraudulent pretenses, representations and promises, and he recommended that the Postmaster General close the mails to Bigler and his various-named concerns. As already stated, the mails were so closed on Nov. 21, 1934.

Correspondence**CONSTITUTION AND HEART
DISEASE**

To the Editor—A recent editorial in *THE JOURNAL* (January 19, p. 221) deals with a publication on constitution and heart disease by Raymond Pearl and Antonio Ciocco, who examined a number of cases of heart disease regardless of type and etiology and found no relationship between heart disease and body build.

Permit me to point out what appears to me to be the basic error that underlies the study of these authors as well as the editorial opinion concurring with their conclusions.

It would be totally unreasonable to any student of medicine to search for a possible constitutional type in a group of cases of pulmonary disease comprising patients with pulmonary tuberculosis, chronic bronchitis, pulmonary neoplasms, lung abscess, pleurisy, pneumoconiosis, emphysema, and other diseases. Such a study would certainly fail to reveal any relationship between pulmonary disease and any single constitutional body type. Such a study would be a waste of time, because it would be expected from the outset to reveal nothing of importance. On the other hand, it is well known that there is a definite relationship between the asthenic body build and pulmonary tuberculosis.

It is just as unreasonable to base a similar study on a group of patients with cardiac disease of all kinds, as the authors did, disregarding the etiology and the anatomic type of the disease.

The principles of cardinal importance in the study of constitutional factors lead too far back into the fundamental sciences of embryology and endocrinology to be entered into here. I deem it important, however, to emphasize the fallacy of a statistical study such as the one referred to.

Another study, which illustrates the correct approach and which has demonstrated observations not at all in accord with those of Pearl and Ciocco, is that of Otto Willner (*Am J M Sc* 180:200 [Aug.] 1930). His observations, based on examinations of 150 Chinese adults, clearly showed the existence of a definite relationship between the asthenic build and mitral configuration of the heart and a large angle of the electrical axis on cardiographic examination.

Statistical studies just for the sake of statistics are one thing. Studies based on thoughtful regard for the type of disease concerned are another.

MARCUS BACKER, M.D., Bridgeport, Conn.

EXPERIMENTAL ACROMEGALY

To the Editor—Although it is a minor matter, I cannot forbear to protest concerning the statement that "one of Evans's students working in Cushing's laboratory at Harvard produced experimental acromegaly" in your answer in *Queries and Minor Notes* (Use of Pituitary Preparations for Increasing Growth, *THE JOURNAL*, February 9, p. 498). The article to which you refer (*Studies in Acromegaly. VIII. Experimental Canine Acromegaly Produced by Injection of Anterior Lobe Pituitary Extract*, *Arch Surg* 18:1708 [part 2] 1929) is by Tracy J. Putnam, Edward B. Benedict and Harold M. Teel. The long experimentation to produce an active extract (*Am J Physiol* 84:157 [Feb.] 1928) and the planning of the work was done by Dr. Putnam, with the fragmentary assistance of Dr. Benedict and (the then) Mr. Teel. Dr. Teel's contributions to endocrinology, and the splendid bulk of Dr. Evans's own work, are such that I know these men would be the first to deplore the inferred or solitary ascription to them of work.

done by another, regardless of the rivalry of experimental laboratories. As a one time fellow in charge of the Cabot Laboratory of Surgical Research, where Dr Putnam's work was done, I should like to ask that this correction appear in your columns.

A J McLEAN, M D, Portland, Ore

Queries and Minor Notes

ANONYMOUS COMMUNICATIONS and queries on postal cards will not be noticed. Every letter must contain the writer's name and address but these will be omitted, on request.

BLADDER PAIN

To the Editor—A woman aged 25 and unmarried has had a bladder ailment for many years. She has frequent spells, apparently of vesical spasm which give her severe cramplike pains. Cystoscopy on several occasions has revealed a normal bladder lining membrane and no pus or organisms are found in the urine. At the times when these pains are present she also has frequency of micturition. During the attacks she obtains some relief from camphorated tincture of opium but her greatest relief is obtained from simple bladder irrigations. About a year ago she had a simple appendectomy at which time a cyst was removed from the right ovary. There was no malposition of the uterus and the pelvic organs were otherwise normal. Since this operation the patient's menstrual symptoms have been somewhat more pronounced and she takes ovarian extract hypodermically at her menstrual time. If this is published please omit name.

M D Alabama

ANSWER—There are several possibilities to consider in determining the cause of the bladder pain.

First, it is important to rule out the possibility of chronic urethritis. The examination for the presence of infection in the urethra should include careful inspection of Skene's glands, stripping the urethra for pus, search for tenderness and, possibly, the exploration of the urethra with diagnostic bougies for the presence of strictures.

It is possible that the symptoms may be due to so-called elusive or Hunner's ulcer of the bladder. As is well known many of these patients have a clear urine, free from pus and organisms and yet, on careful cystoscopic examination areas of ulceration may be seen at one time and at other times the ulcers will be healed and one sees small areas of increased vascularity that bleed when the bladder is fully distended.

It is necessary in an obscure case of this kind to rule out the presence of stone in the ureter by means of a roentgen examination.

Lesions of the upper tract may be ruled out by an intravenous pyelogram.

If the complete survey of the urinary system is negative a complete physical examination should be done to rule out the presence of obscure disease in the central nervous system that might account for the bladder symptoms. This at times is a difficult task calling for the services of an expert neurologist.

Very rarely, bladder disturbance may be due to allergy.

Finally, in view of the fact that the patient has been operated on a careful examination should be made of the pelvis. Every once in a while bladder symptoms may be due to trivial lesions in the cervix as it is well known that symptoms of this kind have disappeared following cauterization of the cervix.

SPEECH TRAINING AFTER CLEFT PALATE OPERATION

To the Editor—My 22 months old baby boy was born with a right complete cleft of the soft hard palate the alveolar arch and the lip. He was immediately placed in the hands of an able surgeon who completed a splendid repair when the child was 14 months old. Now that he has begun to talk he has been unable to pronounce letters that depend on the soft palate. He pronounces m and n well but pronounces daddy as though it were spelled with n and says nang for hang and so on. Will you kindly advise what measures may help in speech training voice culture or phonetics to overcome this impediment?

D K MATTHEWS M D Dresden, Ohio

ANSWER—Perhaps the most important single factor in correct speech is a freely movable muscular sphincter that includes the superior constrictor of the pharynx and a freely movable soft palate. If the soft palate does not completely close, there will be a leak of air into the nose and consequently nasal speech—and, unless corrected the inability to make the hard consonants understood. M and n normally go through the nose. However, trouble in making people understand hard consonants is apt to set up a vicious circle in a child's speech in that he says them rapidly to get it over with and may

become discouraged and even lazy in attempting to overcome the difficulty. This point is illustrated by the child's being able to say mama but not being able to say daddy. The first consideration in the repair is to decide whether further surgery in an effort to lengthen the palate would be of benefit. Whether or not operation is done or is necessary, it is almost always necessary for the child to have careful speech training to get good speech. This is best accomplished by one trained in the work, and most communities nowadays have such a trained worker available either in special institutions or in public schools. Where this is not available, it is probably worth while for the mother herself to arrange a consultation with a speech trainer and learn some of the fundamentals of the methods used. Then it is best to have classes at definite periods with the patient, encourage him, reward him and show him the benefits of clear speech rather than correct him each time he makes an error in speech. It is preferable, if possible, to have this help given by some one outside the family who is not accustomed to the child's speech. The Central Institute for the Deaf, 818 South Kingshighway, St Louis, can probably supply more definite information.

EOSINOPHILIA IN TRICHINOSIS

To the Editor—In trichinosis as the patient improves there is an increase in eosinophilia. While I know that it is a good prognostic sign why should it occur? Please omit name.

M D, New York

ANSWER—T R Brown (*J Exper Med* 3 315, 1898) reports the eosinophil count in a case of trichinosis in which a blood count was made daily, beginning six or seven weeks after the patient reported the onset of symptoms. The count was continued for sixty-nine days. The percentage of eosinophils was 37 on admission, declined to 83 in eighteen days, rose again gradually to a maximum of 68.2 fifty days after admission, or from thirteen to fourteen weeks after the onset of symptoms and declined to 16.8 on discharge of the patient from the hospital nineteen days later.

In trichinosis the percentage of eosinophils increases and the neutrophils decrease as the trichinella larvae migrate from the intestine into the muscles. The increase may continue into the period of convalescence and remain above normal for months or even a year after the initial rise. There is considerable variation in the percentages of eosinophils reported in different cases of trichinosis and at different intervals in the same case. There is no conclusive evidence that the rise always occurs with the onset of convalescence. The migration of larval worms initiates the increase in eosinophils. The rate at which larvae are liberated and the number entering the muscles are both liable to adjustments as the result of environmental conditions in the bowel where the feeding adults occur. The percentages of eosinophils in the blood to some extent represent the cumulative effect of the migrations and the occurrence of a maximum in convalescence is probably a lag effect.

YEASTS IN STOOLS

To the Editor—Can you give me any references on the possible pathogenicity of (or associated pathologic changes with) abundant yeasts in feces that are otherwise normal? An arthritic woman aged 53 who has lived as a missionary in the tropics but who has never had sprue or intestinal parasites so far as known in the past had mucous colitis apparently mild. In a series of five stools examined for parasites (negative) abundant clumps of oval yeasts were found with a few associated pus cells. Eosinophilia (5 per cent) is present. Removal of abscessed teeth and tonsils has shown no marked effect. The basal metabolic rate is minus fifteen.

DELL T LUNDQUIST M D Palo Alto Calif

ANSWER—It is noted that the stools of the patient under consideration are described as containing abundant clumps of oval yeast with a few associated pus cells. Since no report on the cultures of the stools is given it cannot be determined whether the fungus mentioned is a true yeast or a Monilia. Relative to the latter, P M Keating (*Fungus Infection of Bone and Joint* *South M J* 2 1072) reported twenty-five cases of Monilia infections of the bone and joint, of which eight cases were classed under chronic atrophic arthritis. These patients showed a heavy growth of Monilia in the intestine and throat. They also gave positive blood agglutinations and were sensitive to intradermal tests for Monilia. The treatment described was iodides neoarsphenamine, specific vaccine and diet.

Nye Zervas and Cornwall (*The Pathogenicity of Yeastlike Fungi Isolated from the Human Gastro-Intestinal Tract*, *Am J M Sc* 178 515 [Oct.] 1929) investigated the pathogenicity of yeast isolated from the stools of normal individuals and with patients with various diseases. Many of the yeasts isolated were found to be pathogenic to laboratory animals.

SUCTION AND SIPHONAGE IN SINUS DISEASE

To the Editor—Regarding the popular practice of applying suction and siphonage (nasal) as a means of draining the various sinuses, am I correct when I maintain that it is mechanically impossible to obtain such desirable results in that way? My contention is that the developed negative pressure is equal opposite all the sinus openings and that therefore there can be no movement of the contained fluid and that the only way in which retained secretion can be removed requires the entrance of a tube into one of the openings, followed by suction or pressure. Am I correct in this? If printed in *THE JOURNAL*, kindly omit name.

M D, New York

ANSWER—It is in all likelihood true that the popular practice of applying suction and nasal siphonage as a means of draining the various sinuses is only partly, if at all, successful in accomplishing this purpose. The most rational and successful methods depend on the insertion of a trocar or blunt cannula into the cavity in question and then using suction, irrigation or, rarely, pressure. This is not to say, however, that the proper use of suction and siphonage is not a helpful procedure. Even though the secretions removed are those which have already left the sinuses and are present in the nasal cavity, there is some depletion of the tissues following the use of warm solutions, especially if these are hypotonic, and there is often a great deal of comfort to be obtained in the free breathing that follows the cleansing of the nasal passages. Some of the solution used may actually enter the sinuses, but not with any degree of force. After puncture and lavage of such a cavity as the antrum of Highmore, it is not uncommon to find a silver stained secretion when the patient has been using mild silver protein.

EFFECTS OF INHALING SULPHUR DIOXIDE

To the Editor—Can inhalation of sulphur dioxide or other gas used in electrical refrigeration, in sufficient quantity, result in anemia? Are there records of such cases being actually checked prior to such inhalation and following it?

M J STONE MD Bronx N Y

ANSWER—From the action of sulphur dioxide or other commonly used refrigerator gases, an anemia is not expectable. The effects of sulphur dioxide are essentially but not exclusively local and chiefly are represented by inflammation along the respiratory tract. However, some systemic effects are possible under conditions of either severe or moderate involvement, such for example as the consequences attending increased acidity of the body. Under two circumstances an anemia may arise after exposure to sulphur dioxide. The first of these is connected with direful poisoning. The hemoglobin quickly is changed through decomposition to hematin. Such a condition has been discussed in Peterson, Haime and Webster's "Legal Medicine and Toxicology." This, however, is more often associated with fatal cases and the brief time involved scarcely permits of the use of the term "anemia." The second possibility grows out of the fact that a respiratory infection may be associated with more moderate poisoning by sulphur dioxide and, as the result of infection rather than as a direct result, anemia may take place. In short, anemia is a possible but not a characteristic result from sulphur dioxide in particular or from any known much used household chemical refrigerant.

PREGNANCY AND ALLERGIC PHENOMENA

To the Editor—I have just delivered a quadripara of twins and would appreciate a scientific explanation of the following unusual condition. There is nothing unusual in the condition of the mother except for a hypertension of 160 systolic 84 diastolic. The Wassermann reaction is negative, and examination of the urine is negative. The unusual feature is the presence of an urticarial dermatitis, itching in character, with raised surfaces, occurring just after delivery of the placenta. This condition persists till the onset of a following pregnancy. The patient has had this condition following her first delivery up to the present date. As a matter of fact she realized that she was pregnant when the urticarial condition cleared up. Can it be possible that a placental or ovarian hormone deficiency after pregnancy causes this condition? The patient had no disturbance of the skin prior to her first pregnancy.

JACOB GOLDBERG MD Long Branch, N J

ANSWER—The history here related is not at all uncommon. Disappearance of urticaria and pruritus at the onset of pregnancy, with recurrence after the termination of labor. There are many possible explanations.

The correspondent says nothing about the menstrual history of the patient. This, together with investigations as to the hormone content (estrogenic and gonadotropic principles) of the blood and urine in different parts of the menstrual cycle may give some clue as to a hormone deficiency, if such exists. It may be that the patient has a normal hormone balance but that an intercurrent allergic condition exists, the cutaneous mani-

festations of which were relieved by the increased level of estrogenic and/or gonadotropic substances (or even some unknown factor) in the blood stream during pregnancy. It does not follow that therapy with either of these principles would be safe or effective in the interim between pregnancies and obviously, even if effective, it would have to be kept up indefinitely. The possible effects of such therapy on the menstrual cycle must also be considered. The usual efforts should be made to trace in the environment an inciting factor of the urticaria, such as a food to which the patient may be sensitive.

TRIBROMETHANOL ANESTHESIA NOT RECOMMENDED FOR TONSILLECTOMY

To the Editor—Will you kindly inform me whether it is safe to administer tribromethanol to the removal of tonsils and adenoids when this work is performed in the physician's office? May this drug be administered to children? If yes, are there any special precautions to be taken? Kindly omit name.

M D, Connecticut

ANSWER—It is not wise and frequently is actually unsafe to administer tribromethanol in the removal of tonsils and adenoids when this work is performed either in the physician's office or even in a hospital. There are other better and safer anesthetics for this purpose, ether, to mention one of them, being much preferable. Patients frequently do not awake from tribromethanol for hours. This is an undesirable situation when there is a good deal of secretion in the pharynx or vomitus, or when there may be bleeding such as follows from time to time after a tonsil and adenoid operation. The laryngeal cough reflex disappears late under tribromethanol anesthesia and returns late, and it is this laryngeal cough which is the "watch-dog" in Jackson's terminology, of the lungs. Blood and secretion in the pharynx, when the laryngeal cough reflex is absent for periods of time, may enter the lungs and produce serious complications.

The drug may be administered to children in proper doses as it is to adults. Here, too, the same restrictions as to the presence of secretion or blood in the pharynx hold.

LOCALIZED PERSPIRATION

To the Editor—A medical man aged 42 complains of continuous sweating on the left side of the forehead and left side of the nose only for the last month. The family history reveals nothing in particular. The patient has no outstanding habits. He was passing small quantities of sugar in the urine about a year ago for a short time, but there has been none since. The blood sugar is otherwise normal. The dextrose tolerance test reads 0.14 mg of sugar. Physical examination of the digestive, respiratory and circulatory systems was normal. The pulse was 82, the blood pressure 125 systolic, 80 diastolic. The urinary system normal without albumin or sugar. The nervous system normal, without subjective complaint, the eyes normal (fundus) no wasting of any muscles, no tremors, the reflexes all normal. Cutaneous sensations normal. Except for the present subjective complaint of constant perspiration on the left side of the forehead and on the left side of the nose the patient has no trouble. Please advise me of the probable cause of this condition and how to proceed with the case. Kindly omit name.

M D, India

ANSWER—The probable cause of the localized sweating in this case is an irritation of the sympathetic chain in the cervical or upper thoracic regions on the left side. A dilatation of the pupil of the eye on that side would be confirmatory. One of the commonest causes for this condition is an aneurysm of the arch of the aorta. However, any tumor in that region may be the etiologic agent.

HYPERHIDROSIS

To the Editor—What treatment is suggested in a case of generalized hyperhidrosis of ten years duration in a woman, aged 69 who has had a good health record? At present she is showing some myocardial changes with associated dyspnea, bronchitis and hypertension. Examination of the urine gives negative results. Sweating occurs winter and summer, day and night. It is not offensive but keeps the patient's underclothing saturated most of the time. Local applications are not effective. Please discuss etiology also. Kindly omit name.

M D, Maryland

ANSWER—Hyperhidrosis is a functional disturbance of the sweat secretion, which is regulated by the vegetative nervous system. According to some modern physiologists there are two mechanisms involved, one of parasympathetic origin produced by thermic stimulation, and the other of sympathetic origin associated with psychic disturbances. In an elderly woman in whom tuberculosis can be excluded, the etiology may not be an organic condition and it may be purely nervous in origin. Treatment will give only partial relief. Permanganate baths may be tried. Atropine internally is of temporary benefit. The dosage should not exceed 0.001 Gm.

KAHN TEST IN PSORIASIS

To the Editor—I should like to know whether a positive Kahn reaction exists in psoriasis?
N L. MISTACHUKIN M.D., St. Louis

ANSWER.—There is no indication in the literature that the Kahn test gives positive reactions in the absence of syphilis, in cases of psoriasis. Keim and Kahn (*J Lab & Clin Med* 10 1013 [Sept.] 1925), in a study of the specificity of the Kahn test in nonsyphilitic conditions, list thirty-three cases of psoriasis in which the Kahn reactions were negative. Among the cases of psoriasis included in the serologic conferences of the League of Nations Health Committee (Reports of Second Laboratory Conference and of the Montevideo Conference on Serodiagnosis of Syphilis, Geneva, League of Nations Health Organization 1928 and 1931) Kahn reported one doubtful (\pm) reaction in a patient free from syphilis. It would appear that the specificity of the Kahn test is not affected by psoriasis. It is well, however, to be duly guarded in interpreting positive serologic results in the presence of pathologic conditions other than syphilis. This applies to all methods.

TABES WITH OPTIC ATROPHY

To the Editor—A man in his early fifties has been sent to me for treatment because of unilateral optic atrophy. He presents all the classic signs and symptoms of tabes, his blood is 4 plus and he gives a history of an early lesion for which he states he received one injection of araphenamine about twenty five years ago. Would you kindly outline what is considered the latest method of proceeding with the treatment of such a case? What is the present thought about weekly spinal drainage in these cases? What is the place of the different metals here and what form of arsenic is indicated? Please omit name. M D Connecticut

ANSWER.—Neither the "latest" nor older methods can be expected to give any great improvement in such a case. An arrest of the process should be attempted with a return to a negative Wassermann reaction, but no hope of anything more than that should be offered. Mercury or bismuth compounds and potassium iodide in many such cases are as satisfactory as any arsenical. If tryparsamide is used, great care in watching for fundus or field changes in the good eye by weekly tests should be exercised. Weekly spinal drainage is not of proved value.

RECURRENCE OF OSTEOMYELITIS

To the Editor—Please send me any information you may have regarding the possibility and probability of an osteomyelitis recurring fifteen years after the original infection in the femur. Could such a recurrence be spontaneous? Would a blow to the skin over the site of the original involvement cause a recurrence?
M D Florida

ANSWER.—Pyogenic infection in bone may remain latent for many years following an acute osteomyelitis. It is not infrequent that this infection becomes reactivated long after the original disease. The so called silent foci of osteomyelitis may remain in bone for as long as twenty to thirty years without causing active symptoms and are frequently discovered only by roentgen examination. Activation of such a latent infection is usually without obvious cause, but frequently a history of regional injury is obtained. Undoubtedly, in some cases, injury serves to activate the lesion.

WATER SOLUBLE JELLY INCORPORATING
TANNIC ACID

To the Editor—Would you be kind enough to give me a suitable formula for a water soluble jelly to be used for incorporating tannic acid also a suitable antiseptic. This preparation is to be used for scalp burns exclusively—for first aid treatment in beauty shops. A similar preparation is Ameritan prepared by Ely Lilly & Co. Would the tannic acid stain gray or blond hair? Please specify what antiseptics would be used that are stainless.
MEYER L. NIEDELMAN M.D. Philadelphia

ANSWER.—Five per cent tragacanth jelly preserved by the addition of 1 500 salicylic acid can be medicated with 5 per cent tannic acid. While the salicylic acid would be stainless, the tannic acid might darken the hair temporarily.

IPECAC IN COLITIS

To the Editor—One of my patients has requested that I give my opinion on the use of ipecac in the treatment of mucous colitis. I have never had any experience with the use of ipecac in this way and would much appreciate it if you can give me any light on the subject.
M D California.

ANSWER.—Probably the good results reported from the use of ipecac in some cases of mucous colitis have been in patients who had an unrecognized amebic infection. In nonamebic cases of colitis there is no indication for the use of ipecac.

Medical Examinations and Licensure

COMING EXAMINATIONS

AMERICAN BOARD OF DERMATOLOGY AND SYPHILIDLOGY Written (Group B candidates) The examination will be held in various cities throughout the country, April 29. Oral (Group A and Group B candidates) New York June 10. Sec Dr C Guy Lane 416 Marlborough St. Boston.

AMERICAN BOARD OF OBSTETRICS AND GYNECOLOGY Written (Group B candidates) The examination will be held in various cities of the United States and Canada March 23. Final oral and clinical examination (Group A and Group B candidates) Atlantic City N J June 10-11. Sec Dr Paul Titus 1015 Highland Bldg Pittsburgh.

AMERICAN BOARD OF OPHTHALMOLOGY Philadelphia June 8 and New York June 10. Applications must be filed before April 10. Sec Dr William H Wilder 122 S Michigan Blvd Chicago.

AMERICAN BOARD OF OTOLARYNGOLOGY New York June 8. Sec Dr W P Wherry 1500 Medical Arts Bldg Omaha.

AMERICAN BOARD OF PEDIATRICS Atlantic City N J June 10 and St Louis Nov 19. Sec Dr C A Aldrich, 723 Elm St, Winnetka Ill.

AMERICAN BOARD OF PSYCHIATRY AND NEUROLOGY Philadelphia June 7-8. Sec Dr Walter Freeman 1726 Eye St N W Washington D C.

AMERICAN BOARD OF RADIOLOGY San Francisco May 10-12 and Atlantic City N J, June 8-10. Sec, Dr Byrl R Kirklin Mayo Clinic, Rochester Minn.

ARIZONA Basic Science Tucson March 19. Sec, Dr Robert L. Nugent Science Hall University of Arizona Tucson. Medical Phoenix April 23. Sec Dr J H Patterson, 826 Security Bldg Phoenix.

COLORADO Denver April 3. Sec Dr Wm Whitridge Williams 422 State Office Bldg Denver.

CONNECTICUT Endorsement Hartford, March 26. Sec Dr Thomas P Murdock 147 W Main St Meriden.

IDAHOO Boise April 2. Commissioner of Law Enforcement Hon Emmitt Pfost, 203 State House Boise.

ILLINOIS Chicago April 9-11. Superintendent of Registration Department of Registration and Education Mr Eugene R Schwartz, Springfield.

MINNESOTA Basic Science Minneapolis April 23. Sec, Dr J Charney McKinley, 126 Millard Hall University of Minnesota Minneapolis. Medical Minneapolis April 16-18. Sec Dr E J Engberg 350 St Peter St St Paul.

MONTANA Helena April 2. Sec Dr S A Cooney 7 W 6th Ave Helena.

NATIONAL BOARD OF MEDICAL EXAMINERS The examination will be held in all centers where there are Class A medical schools and five or more candidates desiring to take the examination June 24-26. Ex Sec Mr Everett S Elwood 225 S 15th St Philadelphia.

NEW MEXICO Santa Fe, April 8-9. Sec Dr P G Cornish Jr, 221 W Central Ave Albuquerque.

RHODE ISLAND Providence April 4-5. Dir Public Health Commission Dr Lester A Round 319 State Office Bldg Providence.

TENNESSEE Memphis March 25-26. Sec Dr H W Qualls, 130 Madison Ave Memphis.

WEST VIRGINIA Charleston March 18. State Health Commissioner Dr Arthur E McClue Charleston.

Idaho October Examination

Hon Emmitt Pfost, Commissioner of Law Enforcement, reports the oral and written examination held in Boise, Oct 2-3, 1934. The examination covered 13 subjects and included 130 questions. An average of 75 per cent was required to pass. Seven candidates were examined, all of whom passed. Fourteen physicians were licensed by endorsement. The following schools were represented:

School	PASSED	Year Grad	Per Cent
College of Medical Evangelists	(1934)		80
University of California Medical School	(1934)		92
Northwestern University Medical School	(1934)		80

Puerto Rico September Examination

Dr Ramon M Suarez acting secretary, Board of Medical Examiners of Puerto Rico, reports the written and practical examination held in San Juan, Sept 11-15, 1934. The examination covered 17 subjects and included 80 questions. An average of 75 per cent was required to pass. Ten candidates

were examined, all of whom passed. The following schools were represented:

School	PASSED	Year Grad	Per Cent
George Washington University School of Medicine		(1934)	84
University of Maryland School of Medicine and College of Physicians and Surgeons		(1933)	84.7, 85.1
St. Louis University School of Medicine		(1934)	80.8, 84.3
Jefferson Medical College of Philadelphia		(1934)	84.8
Medical College of Virginia		(1934)	83, 85.4
Université de Paris Faculté de Médecine		(1934)*	80.3
Universidad Central de España Facultad de Medicina, Madrid		(1933)*	78

Two physicians were licensed by reciprocity and 2 physicians were licensed by endorsement from September 5 to October 18. The following schools were represented:

Book Notices

The Biology of the Individual. An investigation of the Most Recent Advances. The Proceedings of the Association New York December 28th and 29th 1932. Editorial Board: J. H. James, Hunt M.D., Thomas K. Davis M.D., and Angus M. Franks M.D. Association for Research in Nervous and Mental Disease. Vol. XIV of a Series of Research Publications. Cloth. Price \$6. Pp. 323 with 48 illustrations. Baltimore: Williams & Wilkins Company 1934.

This volume is a compilation of the proceedings of the fourteenth annual meeting of the Association for Research in Nervous and Mental Disease. The papers have been published in full, together with questions and answers as submitted by the commission and members of the association. The first half of the book contains papers on the fundamental factors of heredity, growth, environment and various problems of constitution. This section is particularly instructive and includes such acknowledged masters in their respective fields as Smith Ely Jelliffe, on historical notes on constitution and individuality, C. R. Davenport, on body build and its inheritance, William James, on morphologic form and its relation to reflex action and behavior, T. Wingate Todd, on the progress of physical maturity and mental expansion in childhood, Arnold Gesell, on the ontogenetic patterning of infant behavior, Lewellys Barker, on constitution and internal medicine, Walter Timm, on endocrine aspects of constitution, Max Goldzieher, on biochemical aspects of constitution, and Eugene Kahn, on constitutional aspects of personality types. The second part is concerned with psychologic and sociological aspects of behavior. While these studies have a special appeal to neurologists and psychiatrists, they can be profitably read by every physician desiring to ground himself in those factors which go to make up the biologic totality of the individual. The association has made a distinct contribution to medical literature in making these papers available in book form.

Lungen- und Schwangerschaftskrankheiten. Von H. Braemling, Chefarzt der Fürstengrabenstr. Lungenklinik in Berlin. Paper. Price 24 marks. Pp. 276, with 391 illustrations. Leipzig: Georg Thieme 1933.

The author sets down and draws conclusions from the histories of 215 women suffering from tuberculosis. They had 237 pregnancies (three twins), forty-one miscarriages, seven premature labors, sixty-one therapeutic abortions (of which one abdominal pregnancy and one defundectomy) and there were fourteen cases of pregnancy with tuberculosis before the end of the sixth month, a total of 360 pregnancies. After quoting numerous authorities on both sides of the controversy as to whether pregnancy does or does not aggravate tuberculosis and whether therefore the combination does or does not indicate therapeutic abortion, he enumerates the difficulties in collecting and evaluating such material. He describes a scheme for registering graphically conditions, roentgen observations (pencil sketches), history and result which helps to the understanding of the details of each case quickly. The histories

of the 215 women are given quite fully and his own conclusions are briefly stated at the end of each recital. A careful perusal of many of his case reports permits different conclusions from those arrived at by the author but the reader suffers from the great disadvantage of not having seen and examined and followed the patient, wherefore his deductions are less valuable.

In answer to the question of the effect of pregnancy on the tuberculosis, he says that undoubtedly a bad effect is determinable but that it is not nearly so frequent as has been believed. In answer to the question Which forms of tuberculosis, inactive, active closed, open, are aggravated and in what age? he says that his figures are too few to decide, but it does seem that in young phthisical patients marked augmentation of the severity more often occurs. The answer to the query for the fate of advanced tuberculous patients seems to be more certain: they run less danger than the beginners, because in the latter a curable disease may be made incurable through pregnancy. In the former, pregnancy does not always aggravate the disease. His studies do not permit foretelling in a given case whether pregnancy will or will not act evilly.

The favorable results of treatment are stressed, and the routine roentgen examination of the chest of all pregnant women is advocated. The discussion of therapeutic abortion is clear, both sides being presented, the author admitting that the indication often rests on the doctor's world politics, his operative urgings or his sense of responsibility to either patient, the question at present being a live one in Germany, where increase of population is wanted on ethical and political grounds. Abortion is not done in inactive tuberculosis and in hopeless cases. In young women with active curable phthisis, abortion is done in the first three or four months. Sterilization, the fate of the child, its nursing and other aspects of the complicated situation are given clarifying consideration. This is a valuable addition to the library—already immense—on the subject of tuberculosis in pregnancy.

An Atlas of the Commoner Skin Diseases. By Henry C. O. Semon, M.A. M.D. M.B.C.P. Physician for Diseases of the Skin, Royal Northern Hospital. Photography under the direction of Arnold Moritz, B.A. M.B. B.C. Cloth. Price \$12. Pp. 221, with 103 illustrations. Baltimore: William Wood & Company 1934.

A new atlas comprising 103 plates reproduced by direct color photography from the living subject should prove of great interest to students of dermatology. The photography, under the direction of Arnold Moritz, has been beautifully done. The reproductions are vivid, lifelike portrayals and far superior to those found in most atlases, which have been reproduced from moulages. In a few pictures there has been some slight deviation from the natural colors. In most plates the color values have been faithfully recorded. The cases selected by Semon have been those seen in everyday routine office practice. The accompanying descriptions are brief but contain many valuable diagnostic and therapeutic hints. The author and publisher are to be congratulated on this valuable contribution to dermatologic literature.

Die Variabilität der Organismen und ihre Normengrenzen zugleich ein kurzer Leitfaden der Variationsstatistik. Von Dr. Hans Günther, Professor an der Universität Leipzig. Paper. Price 7 marks. Pp. 132 with 13 illustrations. Leipzig: Georg Thieme 1935.

Morphologic, physiologic and organismal differences are observable between individuals of a species and in a given individual at different times. Of these some are directly measurable, others as yet are not. Notwithstanding these differences, a uniformity prevails that permits the identification of the individual or species. The differences occur, therefore, within limits that it is necessary to recognize. Also a variation beyond certain limits leads to the concepts of normality and disease. The problem of determining the boundaries of normal variation thus becomes of importance from the standpoint of clinical medicine. The author has endeavored to deal with this interesting and significant problem. The causes and categories of variability are described. The statistical methods that permit an analysis of the measurable characters are expounded and their use is exemplified. The determination of 'normal' limits is especially emphasized. Disease as a problem of variability is given a chapter. The bearing of biologic

variables on the concept of "constitution" is discussed. The book is thus of interest to biologists as well as to clinicians. The extent and diversity of the appended bibliography reveal the wide scope of the views presented and their associations and implications.

Standard Classified Nomenclature of Disease Compiled by the National Conference on Nomenclature of Disease. Edited by H. B. Logie, M.D., C.M., Executive Secretary. Second edition. Fabrikoid. Price \$3.50. Pp. 870. New York: The Commonwealth Fund, 1935.

This nomenclature is now in use in some five hundred hospitals of the United States and Canada. In the preparation of the second edition, advice and suggestions have been received from numerous organizations and institutions that have aided in the development of the work and in its application. The standardization of language is a most useful step toward better study of morbidity and mortality. The volume is excellently printed on thin paper and should be made available to record clerks everywhere.

Veröffentlichungen aus der Gavarba und Konstitutionspathologie Herausgegeben von L. Aschoff, M. B. Schmidt, M. Dorst und L. Hek. Geleitet von W. Koch. Heft 37. Band VIII—(Schluss). Heft 5. Kraftverkehr und Volksgesundheit. Gibt es chronische Autoabgaschäden? Experimentelle Untersuchungen am Benzinmotor. Von M. Schmidtman. Paper. Price 4.50 marks. Pp. 44 with 3 illustrations. Jena: Gustav Fischer, 1934.

This study of motor traffic and public health and the question whether there are chronic ill effects from exhaust gas is based on observations chiefly on animals exposed to volatilized German motor fuel (benzene) and the exhaust from motors consuming that fuel. German motor fuel generally consists not merely of gasoline from petroleum but contains also considerable amounts of coal distillate, and coal distillate is rich in benzene and related substances. This study is accordingly concerned less with carbon monoxide asphyxia than with benzene poisoning. In the air of streets the author finds that no considerable hazard to health arises either from carbon monoxide or from benzene. Nor is exhaust gas responsible according to the author, for the increasing occurrence of cancer of the bronchi. Exhaust gas in such dilution as occurs outdoors causes no injury to the lungs. Experiments are, however, reported which afford evidence that the blood-forming organs may be affected and anemia induced by chronic exposure to appreciable amounts of exhaust gas from German motor fuel.

A Collage Textbook of Hygiene. By Dean Franklin Smiley, A.B., M.D., Medical Adviser and Professor of Hygiene in Cornell University, and Adrian Gordon Gould, Ph.D., M.D., Assistant Medical Adviser and Assistant Professor of Hygiene in Cornell University. Second edition. Cloth. Price \$2. Pp. 383 with 80 illustrations. New York: Macmillan Company, 1934.

This is a revised edition of a college book of hygiene that met a most favorable reception on its first appearance. Its authors are experienced in their field and have therefore written the book to the needs of the group for whom it is written. The book discusses the causes of disease, the influence of heredity, methods of prevention of disease, the functioning of various systems in the human body and the proper control of the human body for health.

The New Born Baby. A Manual for the Use of Midwives and Maternity Nurses. By Eric Pritchard, M.A., M.D., F.R.C.P., Medical Director, Infants Hospital, London. Cloth. Price 4/6. Pp. 272 with 9 illustrations. London: Henry Kimpton, 1934.

This little manual was intended to serve as a textbook for students of midwifery. It is a series of lectures on the subject of the care of the new-born baby. The author's style is distinctly informal and direct. Facts are concisely presented but correlated with enough interesting detail so that they engage the reader's interest. The management of clothing and feeding of the new-born baby are first considered. Next, prematurely born infants are considered in detail from the standpoint of care and feeding. The minor ailments and common complaints of the new-born are concisely discussed as are the common diseases of the new-born. While the author reflects the English school of thought, the book is so fundamentally sound in principle that it is well adapted to American instruction. The book will find its greatest field of usefulness among the nursing profession.

Soma Notable Epidemics. By H. Harold Scott, M.D., F.R.C.P., D.P.H., Assistant Director, Bureau of Hygiene and Tropical Diseases. With preface by W. W. Jameson, M.A., M.D., F.R.C.P., Professor of Public Health in the University of London. Cloth. Price \$4.75. Pp. 272. Baltimore: William Wood & Company, 1934.

This volume is concerned wholly with epidemics occurring in England from the period 1854 to 1933. The epidemics include outbreaks of cholera, typhoid, diphtheria, scarlet fever, food poisoning and dysentery. In each instance careful analysis is made as to the mode of onset of the epidemic, the case incidence, the tracing of the spread of the disease and similar factors. The volume should be useful to public health officials and a valuable reference work for students in the field of preventive medicine.

Introduction à la chirurgie réparatrice. Par E. E. Lauwers. Préface du Pr. Ombredanne. Paper. Price 18 francs. Pp. 70. Paris: Masson & Cie, 1934.

The last word of the author, who is a professor at the University of Ghent, is that this is meant to indicate the principles and general application of reparative surgery, leaving the application to those who know how. Professor Ombredanne, who contributes a preface, notes the deliberate absence of surgical technique. The book, therefore, is a painstaking recital of what has been done and by whom, whether on the body surface in the cavities or in relation to organs, members or disturbed functions. The work is thorough and besides being admirably written constitutes an annotated bibliography, including all the literature that is of high significance up to a certain date. What it may lack in completeness can be set down to the rapid progress that has been made recently. It is a reference work of great value not merely to those who adopt the limited view of the specialty but also to the general surgeon, and it has the merit of being compressed within eighty pages.

Medicolegal

Illegal Sale of Drugs Enjoined—The Kentucky board of pharmacy, on the relation of the Attorney General, instituted proceedings to enjoin the Ashland Gem Company, Inc., from operating a pharmacy in violation of the Kentucky pharmacy act alleging that the company was permitting the compounding and dispensing of prescriptions and the vending, at retail of drugs, medicines, poisons and pharmaceutical preparations by persons who were not registered pharmacists. After all the evidence had been introduced and after the case had been submitted to the court for judgment, the plaintiff sought leave to file an amended petition. The court after rejecting the proffered amended petition enjoined the defendant from compounding or dispensing prescriptions and from selling at retail, drugs, medicines, poisons or pharmaceutical preparations except by or in the presence and under the immediate supervision of a registered pharmacist, with the proviso that the injunction should not apply to the selling by the defendant of the usual non-poisonous domestic remedies, medicines, or of patent or proprietary medicines. The plaintiff, contending that the trial court erred in rejecting the amended petition and in refusing to grant the additional relief sought, appealed to the Court of Appeals of Kentucky.

The amended petition, in effect, requested the court to enjoin the defendant from selling at retail except by and under the supervision of a registered pharmacist, a number of preparations named in the original petition or any drug, medicine, poison or pharmaceutical preparation or any patent or proprietary medicine, domestic remedy, chemical or poison which in and of itself is liable to be dangerous or destructive to adult human life in quantities of 60 grains or less for medicinal use. The purpose of the pharmacy act, said the court, is to protect the health and lives of the public against acts of untrained and incompetent persons in compounding and dispensing medicines. That the legislature may, in the exercise of the police power enact such regulatory measures is no longer an open or doubtful question. In prescribing what the defendant may not do, said the Supreme Court, in the conduct or operation of its

drug store, except in the presence and under the immediate supervision of a registered pharmacist, the injunction granted by the trial court practically adopted the language of the pharmacy act. This was as broad and comprehensive as the decree could well be made. It would be an endless task for the court to attempt to enumerate the articles which might be properly included within the scope of different sections of the act. If the sale of any of the preparations specified in the amended petition, except by or in the presence of and under the immediate supervision of a registered pharmacist, would be a violation of the statute then such sale made by the defendant would also be in violation of the injunction. It is therefore apparent, concluded the court that under the decree the plaintiff, as well as the public generally, is afforded every remedy and protection authorized by the statute. The judgment of the trial court was consequently affirmed—*Kentucky Board of Pharmacy v. rel Attorney General v. Ashland Gem Co. (Ky.)*, 71 S W (2d) 1006.

Dead Bodies Liability of Undertaker for Unlawful Detention of Body—An undertaker, over the protest of the surviving wife, held the dead body of her husband and embalmed it without her consent, refusing to deliver the body until his fees were paid. The wife sued the undertaker to recover punitive damages and obtained judgment in the trial court. The undertaker thereupon appealed to the Supreme Court of North Carolina.

The surviving wife, said the Supreme Court, has a property right or quasi-property right in and to the body of her dead husband, which is paramount to the claim of any other person. Moreover, she may recover punitive damages for the mutilation or unlawful detention of the body by a third person if such conduct is wilful, wanton, reckless or unlawful. Manifestly, said the court the arbitrary withholding of the dead body of her husband from a widow as a security for a debt, or for services rendered, is an unlawful act even though courteously done as the Supreme Court of Washington said in *Godbury v. Bleitz*, 133 Wash 134, 233 P 299, 44 A L R 425.

But we think that the holding of the body after the time for its cremation has passed, and claiming to hold it as a guaranty or as security for the payment of some indebtedness is making a misuse of the body, just the same as its mutilation or improper burial. The misuse in one case may be greater in degree but nevertheless it is a misuse.

In the present case the evidence offered by the plaintiff widow tended to show that she, in deep distress from nervous shock, was compelled to wait an hour or two in the dead of the night to haggle and barter for the body of her husband. The Supreme Court concluded that the plaintiff was entitled to recover punitive damages and affirmed the judgment of the trial court—*Bonaparte v. Fraternal Funeral Home (N C)*, 175 S E 137.

Duty of County to Furnish Surgical Treatment to Prisoner—A negro prisoner of Lauderdale County, Tennessee, needed surgical attention that was not available locally. He was sent to a hospital owned by the city of Memphis, carrying two letters, one signed by both the sheriff and the county physician, requesting that he be treated, and the other, signed by the sheriff, saying that Lauderdale County would pay for the necessary treatment. Later the city of Memphis brought suit against Lauderdale County and against the sheriff and the county physician, personally, to recover compensation for the treatment rendered. The trial court dismissed the suit against all defendants but the court of appeals of Tennessee, on appeal, rendered a decree in favor of the city against the county. The case was then carried to the Supreme Court of Tennessee.

In Tennessee, said the Supreme Court, the law requires a county physician to attend prisoners in the county jail and to direct or order treatment. So far, however, as the ordered treatment may not be supplied by the county physician, the prisoner is left to his own resources to provide it, in the same manner and degree as if he were not in confinement. A county physician may not bind the county to pay the cost of medical or hospital service rendered by others to a prisoner. There is no obligation on a county to furnish hospital services to a jail

prisoner who cannot pay the cost of the service. The court concluded, therefore, that there was no statutory authority for holding the county liable for the services rendered by the hospital to the prisoner. The county physician and the sheriff, continued the Supreme Court, were acting in good faith, believing that the county would be liable for the service they requested for the prisoner. The hospital authorities understood that they were not acting individually in their requests. There was no proof that the hospital authorities were without full knowledge of all the attendant circumstances when they rendered the surgical treatment. When public agents, said the court, contract in good faith with parties having full knowledge of the extent of their authority, or who have equal means of knowledge with themselves, they do not become individually liable unless the intent to incur personal responsibility is clearly expressed. The court concluded, therefore, that there was no individual liability on the sheriff or the county physician to pay for the services.

Judgment was entered in favor of the county and of the sheriff and county physician—*Lauderdale County v. City of Memphis (Tenn.)*, 71 S W (2d) 686.

Current Medical Literature

AMERICAN

The Association library lends periodicals to Fellows of the Association and to individual subscribers to THE JOURNAL in continental United States and Canada for a period of three days. Periodicals are available from 1925 to date. Requests for issues of earlier date cannot be filled. Requests should be accompanied by stamps to cover postage (6 cents if one and 12 cents if two periodicals are requested). Periodicals published by the American Medical Association are not available for lending but may be supplied on purchase order. Reprints as a rule are the property of authors and can be obtained for permanent possession only from them.

Titles marked with an asterisk (*) are abstracted below.

Suprarenal Tumors C F Geschickter Baltimore—p 104

Malignant Epithelial Tumors of Neck.—Oliver presents a study of eighty cases of carcinoma arising in the deep tissues of the neck without relation to the epidermis or glandular organs. The ultimate results in relation to the modes of treatment and the types of cellular pathology indicate that these tumors, which are usually fatal (seventy-seven out of eighty cases), are best treated by radical surgery if seen in the earlier stages. They comprise a single pathologic entity grading from the less differentiated basal cell forms through the cuboid cell type to the most highly differentiated squamous cell form. Surgery is slightly more favorable in these last two forms than in the first. Irradiation is probably advisable in conjunction with surgery in all forms, but particularly in the basal cell type. In advanced and inoperable cases, palliative irradiation may be helpful.

Organs of Mice Painted with Carcinogenic Agents.—The Tworts examined the organs of several thousand mice painted with various carcinogenic agents in relation to individual susceptibility to tumor formation. The studies revealed that carcinogenic, therapeutic and other agents may so interfere with the general metabolism of mice that there is a profound influence, direct or indirect on tumor development. Conversely, the presence of a tumor may so derange metabolism, especially of young animals, that cause and effect may be easily confused. It would appear that, in order to avoid errors in judgment, investigators should have a thorough knowledge of the changes likely to prevail among their animals. The observer should be in a position to discriminate between the direct and the indirect effect of a therapeutic or carcinogenic agent, with in consequence an added value to his experimental results. General debilitation and stimulation are it would seem, the key processes to bear in mind. It is when these have been gauged accurately as far as possible, and only then, that one is in a position to evaluate changes in specific tissues. The gen-

eral outcome of the authors observations is that "balance" is the essential in keeping the animal free from malignant disease while at the same time the latter supervenes preferentially on a healthy tissue. Additional observations will, they hope, further enlighten them as regards some of the factors responsible for this balance.

Behavior of Rous Tumor Virus to Freezing.—Miller and Eggers found that the filtrate of the Rous tumor maintained its tumor-producing power after rapid freezing and thawing for sixty times when these experiments were so conducted as to avoid accompanying oxidation. There was no apparent change in its action, as determined by the rate of tumor growth or by the morphology of the tumor, when this procedure was repeated twenty times. With sixty freezings there were delays in the development of the tumor and marked changes in the morphology of the tumor. The filtrable agent of the Rous tumor displays a resistance to freezing and thawing greater than that exhibited by known living agents, such as bacteria or other cellular organisms. To the extent that this throws light on its nature, it would suggest an unorganized character. However, the possibility that the filtrate may contain organized bodies so minute as to escape the effect of sudden and repeated changes of volume cannot be absolutely precluded.

Cerebral Manifestations Following Otitis Media.—Courville and Nielsen point out that a characteristic symptom complex is presented in certain cases following an attack of acute otitis media in early life. The onset of jacksonian convulsions, involving particularly the arm and face, often associated with conjugate deviation of the head and eyes and usually followed by weakness or paralysis of the affected members during a febrile state, suggests a vascular lesion of the cerebrum. Wide variation in the length of the clinical course is noted in these cases. In some instances, the patient recovers within a week, while in cases manifesting probably organic changes in the cortex residual parietic manifestations may persist for months. The vascular pathway of infection is indicated by the abrupt onset of cerebral manifestations. The lesion itself may be toxic, thrombotic or infectious. The toxic lesions are transient. Thrombotic lesions, which result in hemorrhagic softening, may be localized or diffuse. Residual scarring of the cortex probably persists but if this is slight residual paralysis may not be present. If the lesion is or becomes infected, a diffuse nonpurulent or a localized purulent encephalitis (abscess) results. The symptom complex is a manifestation of the localization of a lesion in the central or parietal area, but it does

not indicate the exact nature of the lesion. A similar clinical picture, dependent on hemorrhage or thrombosis following toxic lesions of the arterial walls, may be secondary to acute infectious diseases.

Phosphorus, Calcium and Phosphatase During Healing of Rickets.—Stearns and Warweg observed the serum calcium, the plasma phosphatase and the phosphorus partition in the whole blood and in the serum during the healing of late rickets in two children and over a period of three years in a child whose rickets had healed without a corresponding rise in the level of inorganic phosphorus of the serum. In active late rickets, the organic acid-soluble or ester fraction of phosphorus is definitely low and rises rapidly on addition of vitamin D to the diet. The rise in the ester phosphorus of the corpuscles was observed before the rise in the inorganic phosphorus of the serum occurred. If the amount of vitamin D given is insufficient for rapid healing, the increased level of ester phosphorus may not be maintained. The readily hydrolyzable (ten minute) fraction of the ester phosphorus was not significantly altered from the normal in one patient during the period of active rickets. The level of plasma phosphatase was increased in the blood of both children with active rickets. The values tended to decrease as healing progressed but was still far above normal when roentgenologic healing was complete. In one patient the plasma phosphatase was still double the normal value a year after healing was complete. Roentgenologic evidence of healing was observed in one child before any rise in the level of inorganic phosphorus occurred. The ester phosphorus at this time was still below the normal level but well above the level noted at the first observation.

Phagocytic Power of Whole Blood.—Boerner and Mudd submit a method for direct determination of the phagocytic power of whole blood or plasma-leukocyte mixtures. The following features are embodied to eliminate sources of error in current methods: (1) replacement by heparin of anticoagulants that combine with calcium, (2) a technic for collecting leukocytes from small samples of blood with a minimum of manipulation, (3) provision of an agitator to provide continuous mixing of phagocytes and test objects, and (4) determination of percentage phagocytosis as a function of time. Examples are given of the application of this method to a variety of problems, e. g., titration of the phagocytosis promoting action of therapeutic serum, detection of antibodies following infection

or vaccination, the relative resistance to phagocytosis of different bacterial strains, and inhibition of phagocytosis by soluble bacterial products. The blood of a patient with eosinophilia examined by this method showed phagocytosis by eosinophils, which was, however, quantitatively inferior to that by neutrophils in the same blood. The opsonization of human erythrocytes by human serums of incompatible types, described by Schiff, has been confirmed. Intracellular lysis and digestion of ingested erythrocytes has been observed. The reliability and significance of results obtained with the blood of dogs during the course of experimental pneumococcal infections are examined statistically.

Encephalitis and Myelitis Secondary to Arspenamine Therapy.—Glaser and his associates point out that the mortality of cases with central nervous system involvement secondary to intravenous injection of arspenamine is about 76 per cent. He says there is about one death due to central nervous system involvement in every 5,398 cases treated and in every 28,768 injections. The term "hemorrhagic encephalitis" is not adequately descriptive. The toxic reaction may occur in nonsyphilitic cases and is not related to the quantity of the drug given, to the number of injections, to the toxicity of the drug itself, to the age of the patient or to the sex. It occurs most frequently after the second dose, though it has been reported as occurring after the fifteenth dose. Cases have been reported in which the drug has not at first produced toxic effects but when again given several years later toxic reactions resulted. The symptoms may occur from twelve hours to seventy days after the injection but usually develop in from twelve to 144 hours. The principal symptoms are headache, vomiting, nervousness, chills and dizziness, with physical signs of fever, cyanosis, and respiratory and pulse changes. The principal neurologic signs are convulsions, unconsciousness, pupillary and ocular muscle changes, reflex changes, loss of sphincter control, mental disturbances, hemiparesis and rigidity of the neck. Myelitis and encephalomyelitis may also occur, while meningitis may coexist. This toxic reaction is diffuse rather than focal, as pathologic reports and clinical observations indicate involvement of the other organs. The clinical diagnosis is derived from the organ indicating the greatest involvement: if the brain shows predominating clinical signs, it is an encephalitis, if it is the cord, it is myelitis, if the liver, a hepatitis. The curative measures are detoxification and reduction of intracranial pressure by medical or surgical methods.

Spontaneous Rupture of Esophagus in Syphilis.—In 436 consecutive necropsies performed, forty-four were on patients with syphilitic central nervous system involvement, five of whom, Glass and Freeman state, died during "paretic seizures." Of the latter, two patients died of hemorrhage resulting from complete nontraumatic rupture of the esophageal wall. In no instance were lacerations without complete rupture found. In the first case it was demonstrated that syphilis caused the periarthritis in the esophageal wall. It is logical to assume that these lesions materially weakened the wall. Attacks of retching such as are present in paretic seizures cause extremes of intra-abdominal pressure, which are easily transmitted through the diaphragm to the wall of the esophagus. The regurgitation of autolytic gastric contents over the lining of the esophagus that has been already damaged by the syphilitic reaction tends to erode it, allowing these contents to come in contact with the muscular layers. To substantiate this hypothesis, the epithelial lining round the rent in both specimens was almost completely denuded. In both instances there was a weakened esophageal wall being acted on by autolytic enzymes and severe intra-abdominal pressure, forming an ideal point of rupture. The authors urge a routine, detailed examination of this organ in all necropsies. The esophagus is more vulnerable to pathologic lesions than the statistics have heretofore indicated.

Standardized Technic for Blood Sedimentation Test.—Wintrobe and Landsberg recommend the use of a special hematocrit for the determination of the sedimentation rate because the same instrument can be used subsequently for the measurement of the volume of packed red cells, the volume of packed white cells and platelets, and the icterus index. The determination of the volume of packed red cells is especially

valuable, because by this means the sedimentation rate may be corrected for alterations due to anemia. The following appears to them to be an accurate method of procedure: with a dry syringe and needle, 5 cc of venous blood is collected and mixed in a small bottle containing 4 mg of solid potassium oxalate and 6 mg of solid ammonium oxalate. The blood should be used for the determination of sedimentation rate within four hours. The hematocrit is filled to the 10 cm mark with blood. The upper level of sedimenting corpuscles may be read at frequent intervals or, more simply, a single reading may be made at the end of one hour. Since the sedimentation rate increases with increasing temperature, the sedimentation test should be carried out at a temperature of not less than 22 nor greater than 27 C. The hematocrit should be kept in an exact vertical position during the sedimentation of the blood corpuscles, for, when the instrument stands at an angle of even 3 degrees from the vertical, significant acceleration of sedimentation takes place. After the sedimentation rate has been determined, the hematocrit containing the blood should be centrifuged and the volume of packed red cells determined. The sedimentation rate may then be corrected for alterations due to anemia. The average sedimentation at the end of one hour has been found to be 37 mm in healthy men and 96 mm in normal women. In 86 per cent of the men examined the sedimentation rate ranged from 0 to 65 mm, whereas in the same proportion of women the sedimentation rate ranged from 0 to 15 mm. In an additional 9 per cent the sedimentation rate ranged as high as 9 mm in men and 20 mm in women. These values probably represent the extreme range of normal variation under the foregoing conditions.

Ultimobranchial Body in Human Thyroid.—The examination of forty selected human embryos, from 13 to 55 mm in length, has furnished Kingsbury with no conclusive evidence of the development of thyroid parenchyma from material contributed by the caudal pharyngeal complex. On the contrary, the evidence has indicated that after fusion with the median

thyroid the complex undergoes reticulation and progressive degeneration. Thus there seems to be no justification for substituting the term lateral thyroid for that more usually employed—ultimobranchial body.

Chronic Endogenous Hypoglycemia—Stone cites a case of chronic endogenous hypoglycemia with a neuropsychiatric syndrome. The hypoglycemia is thought to be probably of hepatic origin. The case represents a disease entity, only recently appreciated by medical men, which is probably far more common than the frequency of diagnosis would indicate. The diagnosis will probably be made with increasing frequency as the concept becomes more widely accepted. It should be borne in mind that certain clinical features of the disease and blood sugar determinations are both essential to proper diagnosis. Although the study of the urine may give invaluable information about hyperglycemia or renal function, the urine in hypoglycemia is usually lacking in distinguishing characteristics. A clue may be found in the small proportion of cases with sugar-free acetoneuria, in the absence of other causes. Thus, however, is not pathognomonic and direct blood chemistry is always indispensable to a complete diagnosis.

Venous Pressure—For two years, Leaman has used the direct method of determining venous pressure. The apparatus consists of an 18 gage needle, a special adapter, a 20 cc syringe and an upright manometer tube with a 4 mm. bore graduated in centimeters. Before the determination is made, the patient should rest on an examining table without a pillow for fifteen minutes, during which time the apparatus may be sterilized in 70 per cent alcohol. The patient's arm is prepared and then supported until parallel to an imaginary line in the midaxilla. A cuff of a blood pressure apparatus is placed round the upper arm and inflated to 20 mm of mercury. The apparatus is assembled with the needle on one end of the adapter and the syringe on the other. The stopcock of the adapter must be kept parallel to the needle. As the needle enters the vein, the amount of blood needed for the laboratory is drawn into the syringe and the air is allowed to escape from the cuff of the blood pressure apparatus. The manometer tube is now fitted into the adapter perpendicular to the arm and the stopcock moved up until it is parallel to the manometer tube. Blood will at once start up the tube, and when the column has ceased rising the level on the tube is read. This is the venous pressure, which may be recorded as centimeters of water. To prove the absence of clotting and check the reading, the cuff may be inflated slightly. The column will mount promptly in the tube. When subsequent readings are taken the needle may be introduced on the syringe and adapter or on the adapter alone with the stopcock parallel to the manometer tube. The amount of blood lost at subsequent readings amounts to only a few cubic centimeters. The venous pressure of normal patients at rest in recumbency ranges between 4 and 12 cm of water.

Exercise causes an increased flow of blood to the heart but in the presence of an intact myocardium the demand is almost immediately met. If the heart is incompetent there is a high venous pressure reading after exertion which, if sustained, is indicative of impending cardiac failure. Venous pressure readings will be found to be subject to diurnal variations. They are lower during sleep. The opposite is true in cases of congestive failure. Age does not influence the venous pressure if the previously stated precautions in obtaining the reading are followed. Respiratory variations in the level of the top of the column will be noticed as soon as the first venous pressure readings are made. During inspiration the negative intrathoracic pressure is greater and causes more complete emptying of the larger veins, with a consequent drop in the peripheral venous pressure. The opposite is true during expiration. Single venous pressure determinations, like single blood pressure readings, will prove of little value. It is the venous pressure trend that is significant.

Cystic Tuberculosis of the Bone—Vastine and Bacon report two cases of cystic tuberculosis of the bone. The diagnosis in one was made by biopsy and in the other case clinically and roentgenologically but was not confirmed. The roentgen observations were quite diagnostic. The authors state that cystic tuberculosis of bones in children is due to dissemination of the tubercle bacilli through the blood stream, probably from a caseous lymph node in the chest. There may or may not be swelling over the involved bones. Since these cystic areas are apparently painless, the condition is doubtless more common than the literature would indicate. Routine fluoroscopy of the long bones in infants, examined roentgenologically with a question of tuberculosis in the chest, may lead to more frequent recognition of the condition. The cystic areas sometimes break through the cortex and form abscesses, which rupture through the overlying skin so that sinuses develop. Fever is not necessarily present. It may occur as a result of secondary infection through a draining sinus or as a result of the primary tuberculous process in the chest. There is an associated secondary anemia. Leukopenia and slight lymphocytosis may be found. The blood chemistry is not changed, this being an important diagnostic aid in differentiating cystic tuberculosis from osteitis fibrosa cystica. Diagnosis should be made from roentgenograms, in which the appearance is quite characteristic. The blood calcium and phosphorus are within the normal limits in cystic tuberculosis. A strongly positive tuberculin reaction is important diagnostic evidence. Clinical

or roentgen evidence of an infantile tuberculous process in the chest, particularly involvement of the bronchial glands, was found in the authors' cases.

Healing of Rachitic Bone Changes in Rats—The experiments of Menville and his co-workers definitely demonstrate that young rats, made rachitic, show a marked hypomotility of their gastro-intestinal tracts and that the healing of their rachitic bone changes by the different means employed does not relieve them of their hypomotility even after a period of months when the bones have healed. If the life cycle of these rats is compared with that of human beings it must be concluded that, if the cause of constipation in rachitic rats is due to muscular weakness and relaxation of their gastro-intestinal tracts as evidenced by hypomotility, rachitic patients who have had their bone lesions healed by the various methods employed at the present time are apt to continue to show alterations in the motility of their gastro-intestinal tracts for a long time after they are considered cured of rickets.

Origin of Pilonidal Sinus—Fox presents evidence from studies on the human embryo which indicate that 1. The pilonidal sinus is a derivative of skin ectoderm and not neurogenic or enteric in origin. 2. The structures forming the sinus are derived by a process of ectodermal invagination from the

surface of the skin at the time and in the cells destined to form skin appendages (hair and glands) during the third and fourth months of embryonic life. 3 Its mode of origin and the analogy drawn between this structure and the special "scent" gland in the sacrococcygeal region of birds and amniotes suggest the probability that the sinus represents a vestigial skin appendage developing at puberty—hence the age distribution of pilonidal sinuses. 4 Coccygeal medullary vestiges do not give rise to the pilonidal sinus. They probably give rise to the large cystic and solid tumors that occur usually in infants and the new-born. There is also the possibility that they may play a part in the upward direction which the pilonidal sinus takes. 5 Clinical and pathologic observations are presented and explained by this theory. 6 The coccygeal region may possess several sites for the origin of paraganglioma instead of only Luschka's gland as originally thought. 7 Recurrence following operation for pilonidal sinuses should take place in less than 10 per cent of the cases and is due to the fact that certain of the ramifications are left behind. Since the coccyx is fully developed in the first six weeks of fetal life and has no dorsal arches and since the fourth and fifth sacral vertebrae have only vestiges of the neural arch, it is illogical to assume that the coccygeal medullary vestiges may be included within the sacrococcygeal joint. In operations for pilonidal sinus wherein the coccyx is removed and the sacral stump curetted, the improvement is due to the removal of the contiguous infection of periosteal or bony parts. 8 In the prevention of recurrences, wherever the sinus tract extends to the bony parts, the periosteal and fibrous layers should be carefully stripped off and curetted. Dead spaces and recesses with inflammatory products should be guarded against by preventing too early epithelial bridging of the wound and by careful packing.

Blood Sedimentation Test in Appendicitis—Lesser and Goldberger submit a modification of the Westergren technic allowing accurate Westergren interpretation. Test tubes are prepared, each containing 30 mg of dried sodium citrate; these tubes are kept available in the wards at all times. To perform the test, 45 cc of blood is drawn from a vein, added to a test tube and shaken thoroughly, the test then proceeds as in the original method. However readings were taken at the end of fifteen minutes and at the end of the hour, the final hour reading giving the desired information as to rapidity and intensity of the reaction. The authors' study is based on the observations of 3,000 readings in 2,000 cases. The sedimentation reading in cases of acute appendicitis (catarrhal, suppurative or gangrenous) is uniformly normal. The sedimentation readings in all other acute abdominal conditions are consistently abnormal. Further, the sedimentation readings in all extra-abdominal conditions simulating acute conditions of the abdomen are consistently abnormal. No physicochemical or anatomic explanation for this phenomenon is offered but presents itself as a problem for further study. A significant observation is described and offered as a potential specific aid in the differential diagnosis of acute appendicitis.

Reaction of Lipids in Blood Leukocytes to Infection—Boyd's investigations demonstrate that the white blood cells undergo marked metabolic variations, as indicated by changes in their lipid content, in pregnancy, lactation, postoperative convalescence, fever and convalescence from fever. He presents twenty-six complete differential analyses of the lipids in the leukocytes under fasting conditions in twelve cases of fever. In each analysis the lipids determined were free cholesterol, ester cholesterol, total cholesterol, phospholipid, neutral fat, total fatty acids and total lipid. Oxidative micromethods were used. In patients who recovered normally from fever due to a variety of causes, the white blood cells contained large amounts of phospholipid. There was generally also an increased value for free cholesterol with low figures for ester cholesterol and neutral fat. In these, convalescence was accompanied by a further rise in phospholipid. Patients who died as a result of their infection were noted to have low phospholipid values in the blood leukocytes during the febrile period. The same was found true in a case of thrombophlebitis when complications developed. The activity of the white blood cells may be measured by determining their lipid content, especially the

phospholipid fraction. Data from one case suggests that a blood transfusion may increase the activity of the white blood cells.

Pathologic Basis for the Disabled Back—Carpenter states that injury to the intervertebral disk, whether the result of disease or of trauma, either acute or chronic, must be given consideration as the pathologic process responsible for any back disability. The intervertebral disk injury is not revealed by roentgen examination, but the resulting vertebral changes produce characteristic roentgen appearances. Intervertebral disk injury manifests itself most frequently as (1) retropulsion of the nucleus pulposus into the spinal canal, (2) prolapse of the nucleus pulposus into the adjacent vertebral body, (3) localized vertebral osteo-arthritis, (4) generalized vertebral osteo-arthritis, (5) thinning of the intervertebral disks, with or without wedging of the vertebral bodies, and (6) biconcave vertebral bodies and spherical disks. Since the knowledge of the intervertebral disk has recently been greatly advanced, one is often able to find a disturbance of the intervertebral disk as the pathologic basis for the disabled back.

Undistorted Radiography in Obstetrics—To avoid distortion of the image within the limits of practicability in obstetrics, Buchner suggests that teleroentgenograms be taken, particularly lateral teleroentgenograms. These will record ante partum signs directly and without bias. He recommends the use of the six-foot tube distance, 10 milliamperes at from 90 to 110 kilovolts peak for forty seconds with the Potter-Bucky diaphragm. The patient should lie on her back at a right angle to the path of the ray with the casset held vertically to assure a true lateral picture. There will be no magnification of the image necessitating correction, and the most important measurements may be taken directly from the one roentgenogram. The fetal biparietal diameter is the cephalic diameter desired, and the one usually found, and the anterior or posterior tendency of the fetal spine is readily seen in both vertex and breech presentations. The thickness of the maternal soft parts separating the fetal and maternal bony structures can frequently be clearly traced. The true conjugate can be measured from the sacral promontory to the anterior-inferior border of the superimposed acetabular rings, as this represents the inner or obstetric surface of the symphysis pubis in the roentgenogram. In this manner, no special apparatus or difficult patient position is necessary, only one 14 by 17-inch film is used, and from that the most important diameters are read directly with an ordinary centimeter ruler.

Urea Clearance Test in Children—Payne and Shukry examined thirty-nine children suffering or convalescent from diseases not involving the renal tract. The urine was tested and was normal in all but one child who was passing albumin and had hemophilia with no history of renal involvement. The average for children is higher than that for the adult and the zone into which most cases fall is also greater (80-140 as against 80-120). In examining the results applied to individual cases, the authors found that no normal case failed to exceed in at least one test the minimal value. McLean's test was applied to the same group, and in all but one values of more than 25 per cent of urea were obtained in one or more specimens indicating a normal function. In the one failure the highest value was 24 per cent and this was in the same case of hemophilia. Another group of thirteen children having some disease involving the kidney were examined by each test. There was no great difference between the two clearance tests but in three cases doubtful results according to the standard test were definitely abnormal in the maximal test. McLean's concentration test gave normal results in six cases in which the maximal test gave an abnormal response. Therefore it is apparent that the capacity of the kidney to excrete urea decreases earlier in disease than the capacity to concentrate urea in the urine. The urea clearance test is more likely to detect early loss of kidney function than is McLean's concentration test.

Pollen Sensitiveness in Children with Asthma—To estimate the frequency with which pollen sensitization occurred in asthmatic children, Pearson examined 250 unselected children attending the asthma clinic. The children examined were divided into four groups: (1) those whose asthma occurred at all seasons of the year, (2) those who were worse in the summer, (3) those who were worse in the winter, and (4) those whose symptoms had not been present for a sufficient length of time to allow classification. Grass pollen is of greater importance in the precipitation of asthmatic attacks than is generally recognized. Of the children tested, 42 per cent gave skin reactions to pollen. A series of thirty-three children of the same age group not suffering from any allergic condition, attending the general medical outpatient clinic, were tested with the same extract, and none of them gave any reaction. If the asthmatic groups are subdivided according to age, an increase in the number of cases giving positive reactions occurs after the age of 9 years. This is in accordance with the well recognized fact that sensitiveness to inhalants becomes more marked as childhood advances. When sensitiveness to pollen was considered in relation to the mode of onset it was found that the groups who have or have had allergic eczema (20 per cent of the series) show the highest proportion of reactors (66 per cent). The capacity for sensitization to allergens of all types seems to be far higher in this than in any other group. For example, 42 per cent stated that they were clinically sensitive to certain foods compared with 12 per cent of the remainder. 22 per cent were clinically sensitive to egg compared with 4 per cent of the rest. The group of apparently pure spasmodic asthma gives the next figure of 42 per cent, while those patients in whom asthma followed a respiratory infection (such as bronchitis, whooping cough or pneumonia) give 34 per cent positive responses.

Relapse in Scarlet Fever—Anderson shows that the development of immunity after an attack of scarlet fever is not invariable by the occurrence of second attacks and relapses. Second attacks developing some months or years after the first attack are according to Rolleston more uncommon than relapses, yet it is noteworthy that, of the admissions in 1933 to the Leeds

City Hospital, 35 per cent gave a history of a previous attack. As regards relapses the same authority, after making allowance for errors in the original diagnosis, estimates that a return of all the characteristic symptoms of the disease occurs in about 1 per cent of all cases. The relapse rates for the Leeds City Hospital for the years 1931, 1932 and 1933 were 3.6, 4 and 4.3 per cent respectively. Such rates appear to be high and they give rise to an administrative problem, as they indicate an additional burden on the available accommodation of the hospital and a definite increase in the cost of treatment of scarlet fever. The author suggests the administration of scarlatinal toxin as a logical procedure in the prevention of relapses.

Visual Disturbances in Toxemias of Pregnancy—Wright and his co-workers assert that practical blindness associated with normal eyegrounds may follow the eclamptic state, the presumption being that the injury has acted at a higher level than the third neuron. The loss of vision may also result from an injury acting at the retinal level either suddenly (usually recovered in whole or in part) or gradually and permanently (owing to late changes in the vessels). Minor injuries may take place involving the retinal vessels, as evidenced by hemorrhages, edema and alteration in the caliber of arteries and veins without immediate interference with vision, such are relatively common. The lesser spastic phenomena of the arteriolar tree described of recent years were probably missed in the authors' cases, owing to the hurried nature of the ophthalmoscopic observation, rather than absent, on account of any peculiarity in the local conditions. Detachment of the retina as a sequel to the toxemias of pregnancy has not been observed by the authors in the last ten years.

Weil's Disease—Davidson and his associates discuss nineteen cases of Weil's disease, in fifteen of which the clinical diagnosis was confirmed by bacteriologic or serologic tests. Thirteen of the patients were employed in the handling and cleaning of fish. These observations show that workers among fish must be included in the occupational groups especially liable to Weil's disease. Favorable results have been reported following the administration of specific antiserum in the early stages of the disease, and also in cases with commencing icterus. The best results, however, are obtained when serum is given within the first three days of the onset. Since jaundice does not appear regularly before the fifth day, the clinical diagnosis depends on the recognition of such symptoms as abrupt febrile onset, muscular pain, "red eyes" and marked prostration. None of these symptoms, however, can be held to be specific for Weil's disease, since they may occur in many acute infections.

This is particularly true of influenza and acute tonsillitis. While it is true that the occurrence of a sudden acute fever in a sewer worker might suggest the possibility of leptospirosis, even in the preicteric stage, the problem is entirely different in workers connected with fish curing and cleaning. For every case of Weil's disease occurring among the thousands of fish workers in Aberdeen there must be hundreds of cases of acute febrile illness of other origin with similar symptoms to those mentioned previously. Weil's disease in the early stages might be suspected on the following additional grounds: a leukocytosis with a shift to the left in the polymorphonuclear series, latent icterus with a direct or biphasic van den Bergh reaction, acute nephritis unassociated with edema or hypertension but indicated by slight albuminuria, the presence of granular and cell casts in the urine and a raised urea or nonprotein nitrogen content in the blood. The tests required to obtain the foregoing data, as well as guinea-pig inoculation with blood, would be impossible in view of the numbers concerned, hence it appears to the authors that the clinical diagnosis in the early stage, before jaundice occurs, presents almost insuperable difficulties. Accordingly, the full benefits of specific serum treatment are unlikely to be realized. In view of the practical difficulties connected with guinea-pig inoculation of blood and urine, the seroreaction will remain the chief method by which the diagnosis will be confirmed finally. Since a positive seroreaction does not occur before the seventh day of the disease, the information obtained is of little value in regard to treatment. Schuffner's investigations indicate that this reaction in Weil's disease is as specific as the Widal reaction in typhoid. The authors' experience is in keeping with this, since serums from 180 cases other than those of Weil's disease have been examined, and in no instance has the reaction been obtained even in a dilution of 1:10.

Relation of Pituitary to Action of Insulin and Epinephrine.—The experiments of Cope and Marks on rabbits confirm the evidence that the anterior lobe of the pituitary plays an important part in the normal glycogenolytic action of epinephrine and that in its absence the glycogen of the liver at any rate, becomes resistant to mobilization by epinephrine. Their observations show that after removal of the pituitary body the adrenals respond normally to insulin hypoglycemia by liberating epinephrine into the blood stream, yet this epinephrine fails to restore the lowered blood sugar to the normal level, in spite of the presence of ample reserves of liver glycogen. The

hyperglycemic response to injected epinephrine is likewise diminished. Converse changes, viz., a resistance to insulin and an increased response to epinephrine, are produced by injection of a suitable extract of the anterior lobe of the pituitary. The foregoing changes are explained on the supposition that the anterior lobe of the pituitary contains a principle which renders the glycogen stores of the liver, and possibly also those of the muscles (now under investigation), susceptible to the mobilizing action of epinephrine. The changes following removal of the hypophysis cannot be reversed by the administration of thyroid, and hence they are not due to the concurrent thyroid degeneration. Conversely, the changes produced by the injection of anterior pituitary extract are not prevented by the removal of the thyroid.

Diagnosis and Treatment of Allergies.—Pratt-Johnson discusses the preparation and use of various group protein solutions consisting of twenty-five compound extracts for diagnosis and treatment of hay fever and asthma. The cutaneous or scratch test is recommended for general adoption. General reactions are much less likely to occur with the scratch test than with the intradermal. Dilute solutions and limitation to six or eight tests at one sitting are essential if the intradermal method is used. Treatment with a series of graduated doses prepared from all the extracts which give positive tests is recommended, beginning with an initial dose of $2\frac{1}{2}$ units. Increasing doses are given at intervals of three or four days up to 60 units, and then further doses at intervals of from five to seven days up to 250 units. At least twelve to fifteen doses should be given. Further maximal doses are then advisable at monthly intervals. Treatment should be commenced as soon as the diagnosis is made. Peptone solutions, mixed B. coli and streptococcus vaccines and other substances may be used non-specifically to reduce sensitiveness to foreign proteins generally. In asthma following infectious catarrhs, the removal of foci of infection and treatment with autogenous vaccines is recommended. It is advisable, in these cases, to exclude other causes by carrying out skin tests.

- *Synchronous and Rhythmic Myoclonic Syndrome G Guillaum and P Mollaret—p 57
*Chronic Intoxication by Manganese Compounds Manganous Parkinsonism L Lyon Caen and A Jude—p 60
Studies on Postinsulin Hypoglycemia in Diabetic Patients J Peusson and J Wohl—p 63

Myoclonic Syndrome—Guillaum and Mollaret discuss the rare condition of myoclonia. Three conditions appear able to inhibit such myoclonias. The first is voluntary muscular contraction, but this exists only in certain patients and often only at the beginning of their illness. The other two are paralysis and perhaps contracture. Synchronism constitutes the final characteristic of these myoclonias. Anatomic studies indicate that in three fourths of the cases the etiology is vascular. More rarely sclerosis, epidemic encephalitis, tumors and other causes may be etiologic. The location of the lesion is circumscribed. One observation localized the lesion exclusively in the two olivodentate complexes. The involvement of these bulbar olives was most striking and predominant at the level of the caudate portion of the principal olive, the endociliary and periciliary myelin sheath of which had almost entirely disappeared. The neuroganglionic cells were diminished in number and showed bulbous degeneration and nuclear bipartition. The vessels of the olivary region showed lesions of intense perivascular inflammation, which were found in an attenuated form outside the olives. To these olivary lesions were added involvement of the olivodentate fibers and especially of the dentate nucleus. These showed a degeneration of the extraciliary interlacing fibers and an abnormal pigmentary infiltration of the cells.

Intoxication by Manganese Compounds—Lyon Caen and Jude state that the use of manganese in France is relatively infrequent since it must be almost entirely imported. Most of the mineral is in the form of oxides and it is used principally in iron metallurgic and grinding factories. The route of toxic absorption is poorly understood but may be digestive, respiratory or even cutaneous. The action on the nervous system appears to be an encephalomyelitis with predominating involvement of the central gray matter—cellular degeneration in the lenticular and caudate nuclei with vascular and perivascular lesions. The action on the liver is acute hepatitis with necrosis blood effusion and beginning cirrhosis. In small doses manganese may be substituted for iron in the blood producing an increased number of cells and hemoglobin, but grave and fatal anemia may occur from large or continued doses. Little is known of its accumulation in the body. It is eliminated by the bile and feces and slightly in the urine. The characteristic symptomatology is parkinsonism. Six groups of symptoms are almost constant: (1) difficulties in walking with muscular hypertonia, rigidity and disorders of coordination, (2) modification of the facies, (3) changes in the voice, (4) shaking, (5) subjective sensory disorders, and (6) psychic disturbances. No cases of death have been reported. Treatment should be based principally on rapid and complete removal of exposure to manganese. Proper hygiene and legislation are important factors in prevention.

Dysenteric Vulvovaginitis—Teveli observed two cases of pyuria caused by the Flexner bacillus. The dysentery bacillus produces in the intestine a suppurative inflammation. Involvement of the urogenital system may occur because the frequent stools expose the vulva to contact with the feces. However, since in two other cases the pyuria was preceded only by a mild colitis, he considers an ascending infection more likely. In a girl, aged 1, it was found that the vulvovaginal discharge was only an accompanying symptom of the dysentery for it was cured within two weeks and the dysentery persisted after

that. The bacterial strain yielded by cultures from the vaginal pus proved to be a bacillus of the Flexner Y group. It was agglutinated by the serum of the Flexner Y, the paratyphoid bacillus up to a high titer. It split mannite and maltose but not saccharose and it did not cause coagulation of milk. The strain yielded by cultures from the stool was of the Shiga-Kruse type. It was agglutinated by the Shiga-Kruse serums up to the final titer, but it did not grow in bouillon and on milk culture mediums it produced flocculation within two weeks (atypical Shiga-Kruse strain). These observations indicate that the strain in the stool differs from that in the vaginal pus. It is possible that the stool also contained Flexner Y bacilli, which escaped discovery, or it is possible but not probable that the vaginal and fecal strains were identical and assumed different characteristics only because they existed under different conditions. The author points out that such a mutation of the various dysentery types, although considered possible by some investigators has not been proved.

Evacuation Disturbances of Stomach During Childhood—Hainiss thinks that in children with lack of appetite the gastric function is not given sufficient attention. For the purpose of examination, the feeding of bismuth paste, against which children often have an aversion, is not necessary and drinking of 0.1, 0.2, 0.25 or 0.3 liter of milk is sufficient, for transillumination reveals whether evacuation progresses satisfactorily or not. Ordinarily the stomach evacuates these quantities of milk in from two to three hours, while in children with lack of appetite the stomach may still be partly filled at the end of this period. To overcome this disturbance the physician should pay attention to the following factors: 1 The composition of the diet should be such that evacuation is facilitated. 2 The intervals between meals must be arranged for the slow evacuation, that is, they should be of sufficient length (at first six hours and later four hours). 3 Attempts should be made to increase the tonus of the stomach by means of medicaments. After the meal the child should rest so as not to burden the hypotonic stomach by the weight of the gastric contents. During the night a Priessnitz compress should be applied. The alkaloids of cinchona bark as well as quinine increase not only the function of the muscular elements but act also as a general tonic.

Evaluation of the Donor Through Determination of His Psychic-Physiologic Status—Chvilivsky studied the effect of single and repeated withdrawals of blood on the central nervous system of the donor. He submitted ninety-six donors to the following tests: (1) testing of steadiness of the hand by means of a tremometer, (2) cephalographic studies consisting of kymographic recording of swaying of the body while in the erect posture, (3) determination of the power of mental concentration by solving arithmetical problems, (4) determination of the blood pressure with simultaneous counting of the pulse in order to obtain the amplitude-frequency index, and (5) determination of the skin temperature. The following conclusions were arrived at: 1 Periodic withdrawal of blood in persons without decidedly pathologic reactions is not injurious. 2 The occurrence of certain neuropsychic alterations makes it inadvisable from a social point of view to draw donors from certain occupations. 3 Because the finer functions are most sensitive to loss of blood, the utilization of skilled mechanics or of motor truck drivers is not desirable. 4 Neurotic subjects with pronounced motor and vegetative disturbances are to be excluded. 5 The amount of the blood to be withdrawn depends on the body weight as well as on the question of whether or not this is the donor's first experience. 6 Withdrawal of the following amounts were found to be well tolerated: from 2 to 3.5 cc per kilogram of body weight on the first withdrawal and from

4 to 6 cc per kilogram in habitual donors 7 Rest after giving of blood accelerates the return to the normal psychic-physiologic status 8 The return to normal psychic-physiologic status takes place quicker after the first withdrawal of blood than after repeated withdrawals All the alterations noted were most pronounced on the seventh day The explanation offered is that at this time an energetic regeneration of blood elements takes place, depriving the organism of a certain amount of oxygen The central nervous system, being most sensitive to oxygen deprivation, shows a lowered capacity for the performance of highly differentiated mechanisms

Gastro-Intestinal Peristalsis After Operations—Matyas made roentgenologic studies of the gastric and the intestinal peristalsis by administering barium sulphate by mouth immediately after the operation He found that emptying of the stomach was delayed for at least ten hours and, after operations on the stomach, for fifty-two hours Early oral administration of water following an operation may therefore result in acute dilatation of the stomach This is particularly likely to happen after partial gastric resection The author advises abundant preoperative administration of water but warns against this for at least from twelve to twenty-four hours after any surgical intervention The water in the meantime may be supplied by the rectal and hypodermic routes

Transfusion of Blood of Pregnant Women—Ehrhardt and Winkler point out that Ehrhardt employed the transfusion of blood of pregnant women in patients with amenorrhea a number of years ago but the results were not entirely satisfactory Claiberg and Siebke employed the transfusion of pregnancy blood in pathologic genital hemorrhages that were caused by persistence of the follicle, for it was Claiberg's aim to destroy the persisting follicle by large amounts of the hormone of the anterior lobe of the hypophysis Siebke, in his studies on the hormone foundations of pathologic genital hemorrhages, came to the conclusion that the combined administration of a hormone extract of the anterior hypophysis and of 100 cc of pregnancy blood made surgical intervention unnecessary in many instances The authors employed injections of pregnancy blood within the last four years in twenty-five patients with glandular hyperplasia The quantities of blood varied between 500 and 1,000 cc In ten patients it was possible to observe the results for two years or longer, and the histories of these patients are reported In three patients the treatment failed in five a permanent normalization of the menstrual cycle was attained, in two others the treatment was partly successful These results indicate that the treatment represents a therapeutic advance, at least in regard to the genital hemorrhages caused by persistence of the follicle The authors assume that the results of this treatment are largely due to the anterior pituitary hormone content of the pregnancy blood, and they think that, when pregnancy blood is not available, concentrated hormone preparations of the anterior hypophysis may be administered However, in patients who have lost a large amount of blood, transfusion is the better method, since it supplies blood, hormones and other stimulating factors

Influence of Spleen Extract on Thrombocytes and Erythrocytes—Haenlein and Schliephake made studies with a spleen extract from which most of the protein substances had

been removed without destroying the physiologically active substances They tested and standardized the extract by sensitization of the vagus of rabbits or by increasing the phagocytosis of human blood With the latter method they were able to detect extremely small quantities To determine the action of the extract on the blood they made their tests on healthy persons who applied for a health certificate, on persons who were in their fourth week of treatment for duodenal ulcer, on patients with nervous heart, aortic defects or asthma, and on persons taking a reducing treatment The persons had to fast during the entire duration of the test First blood was withdrawn for the determination of the normal coagulation time and to detect the normal number of erythrocytes, leukocytes, thrombocytes and reticulocytes Then 2 cc of the spleen extract was injected subcutaneously The coagulation time was determined 5, 15, 30 and 60 minutes after the injection and later every 30 minutes until 210 minutes had elapsed since the injection The erythrocytes, leukocytes, thrombocytes and reticulocytes were counted 30, 90 and 150 minutes after the injection of the extract The authors observed that the spleen exerts a regulatory influence on the coagulation, that the erythrocytes and thrombocytes increase in healthy persons, that the action on the leukocytes is variable, and that the reticulocytes remain uninfluenced They conclude that, in the defense against disease, the spleen not only increases the phagocytic power but also contains hormone-like substances that exert their influence on the composition of the blood

Function of Fluorine in Human Organism—Michaels points out that studies have disclosed that fluorine is a constituent of bones but that it decreases with advancing years It has been assumed that the greater brittleness and the poorer healing tendency of the bones of older persons has some connection with the lesser fluorine content The quantity of fluorine, when compared with other constituents of the bone, is extremely small, but it may play the part of a catalyzer He calls attention to the work of Gautier and Clausmann Gautier was of the opinion that fluorine is a sensitizer for phosphates and that it enables the phosphorus compounds to combine with the tissues This means that the presence of fluorine is essential for the formation of calcium phosphate in the tissues This factor is important in the treatment of calcium deficiency of the skeleton, and he is now engaged in research on this problem He calls attention to factors that indicate an antagonism of fluorine and iodine in the organism to the deleterious effect of the use of iodine on fractured bones, to the possibility that an excess of fluorine as well as a deficiency of iodine may play a part in endemic goiter and to the fact that small doses of iodine have been found helpful in counteracting the symptoms of arteriosclerosis The antagonism of fluorine and iodine suggests the possibility of treating iodine idiosyncrasy with a fluorine preparation

*Oil of Chenopodium in Treatment of Ascariasis During Childhood Schulz-Schmidtborn—p 47

Results of Encephalography in Epilepsy A Wand—p 48

Vaginal Insulin Therapy in Erosions of Uterine Cervix—Klasten states that for years he has treated erosions of the uterine cervix by means of vaginal insulin therapy and obtained favorable results The erosions were usually a symptom of cervicitis, but there were also ulcerations in women with prolapse The treatment was most effective in those developing as the result of the abnormal position of the uterus when the cervix is pressed against the posterior wall of the vagina The erosions observed were frequently of the coarse papillary form, and on first inspection they occasionally made carcinoma seem possible These and other types of erosions responded favorably to local insulin therapy At first the erosions or ulcerations were painted twice daily with insulin and then a tampon was applied that had been saturated with insulin Later the painting was done only once a day or every second day The diet provided rather large quantities of car-

bohydrates. The author observed repeatedly that the formerly regular menstruation was retarded after the local insulin therapy. He never observed hypoglycemic manifestations, but he considered it advisable to study the behavior of the blood sugar following local insulin therapy. There is a slight resorption in vaginal application of insulin, especially if erosions exist, however, it is not sufficient to warrant this method in treating patients with diabetes.

Oil of Chenopodium in Ascariasis.—Schulz Schnudtborn maintains that ascariasis is more frequent in children than is believed and that its symptoms are often mistaken for appendicitis. He emphasizes the necessity of examining the stool for ova. He has used oil of chenopodium with favorable result for years and he has never observed cases of fatal idiosyncrasy or poisoning. He thinks that, if poisoning does occur, it is because no purgative is given with the oil of chenopodium or the purgative is not given in adequate doses. He considers castor oil the most suitable purgative but thinks that, if the medication is left to the parents, castor oil may not be given in sufficiently large doses, since the children are unwilling to take it. To avoid this, he advises simultaneous administration. He recommends the following prescription: oil of chenopodium, from 0.2 to 1 cc., sucrose, 1.5 Gm., oil of cinnamon 3 drops, oil of peppermint, 1 drop, castor oil, sufficient to make 90 cc. This prescription is administered on two successive days. Without evacuating the bowel on the evening before, the children are given at 8, 10 and 12 o'clock in the morning one dose (spoonful) of the prescription. The size of the dose depends on the age, weight and the general condition of the patient. Before the mixture is administered it should be warmed up and well shaken.

Detachment of Retina and Accidents.—Schieck points out that, if detachment of the retina follows a perforating injury of the eyeball or a severe blow to the eye, the development of the detachment is usually quite clear. However, if the detachment takes place spontaneously, it is more difficult to understand the mechanism. Certain diseases of the eye result in conditions that make a detachment more likely, but there are also cases of detachment in which previous disease of the eye cannot be proved. These cases of detachment are often referred to as 'primary.' Nevertheless, the opinion predominates that in the latter cases the true factors are only obscure and that a real 'primary' detachment does not occur. From the point of view of accident compensation, there are patients who report a relatively slight trauma as the cause of the detachment, such as the dashing of a branch against their eye or being hit in the eye by the tail of a cow, which as a rule leaves no outer signs on the eye. The conditions are more obscure when the patients state that the ocular symptom appeared first after an extraordinary physical exertion, during which there was a rush of blood to the head. In such cases it is difficult for the physician to decide, for a satisfactory decision is possible only if the factors are understood that produce a predisposition to the detachment of the retina. The author is convinced that in a completely healthy eye such causes do not result in the detachment of the retina, and he thinks that a predisposition must exist. He concludes that, when certain predispositions have been produced, even comparatively slight traumas or extraordinary physical exertions are sufficient to produce a detachment of the retina. He thinks that in cases of this nature the patients are entitled to accident compensation and opposes the decision rendered by zur Nedden, who virtually rejects the recognition of compensation claims in such cases. The author shows that zur Nedden justifies

his attitude on the basis of a theory that is a complete contradiction to the opinions held by all other ophthalmologists who have studied the problem of detachment of the retina.

Serotherapy in Brucella Abortus Infection.—In Brucella abortus infection, Hilgermann obtains specific serum by immunizing rabbits with a dextrose-bouillon suspension of a concentration of 20 cc of blood withdrawn from the vein of the patient. In order to activate the immunization, he adds to the blood suspension before injecting a small amount of a suspension of two cultures of Brucella abortus. During the course of the immunization the blood concentration is kept in the anaerobic apparatus at 37 C. Two rabbits are given on two successive days intravenous injections of 2 cc. each of the blood concentration plus the bacilli. After a one day interval they are given another injection, and after that two more injections at three day intervals. Three days after the last, the fifth, injection the blood is withdrawn from the animals and the serum extracted from it. The serum (50 cc.) is injected on two successive days (25 cc. each time). Immediately following the intramuscular injection of the serum, the patient whose history is reported developed fever, but four days later the temperature became normal and the general condition improved. A repetition of the Gruber-Widal reaction several weeks later was negative. During the time the serum was prepared and also after the injection of the serum, the formation of antibodies was stimulated further by injecting at seven day intervals 0.5 cc of a weak vaccine consisting of the centrifugate of the blood concentration, to which had been added the suspension of two strains of Brucella abortus. The author reaches the conclusion that by specific serotherapy, supported by vaccino-therapy, even the most severe cases of Brucella abortus infection can be cured.

*Causal Treatment of Poliomyelitis E. Barla Szabo—p 81

Vasoconstricting Action of Rabbit's Blood.—Korschegg found that the blood of normal rabbits exerts a vasoconstricting action on the surviving human artery, beginning at a dilution of from 1 1,400 to 1 1,700. The blood of rabbits with hypertension produces contraction at higher rates of dilution. Depending on the degree of hypertension, contraction is produced by dilutions of from 1 1,700 to 1 4,000. The same proportionate relation between blood pressure and contracting capacity of the blood could be demonstrated also in the serum. The vascular contraction is not caused by epinephrine, but in rabbits with hypertension as well as in those with normal pressure the contraction is caused by so called constrictines.

Velocity of Blood During Valvular Lesions.—To determine the types of stasis in the various valvular lesions, Elias and Laub decided to study the circulatory velocity in compensated cardiac defects, because it has been demonstrated that the decompensated cardiac lesions have a retarded circulation time. The authors wanted to determine whether the two cardiac defects, which clinically as well as physiochemically (oncotic pressure) presented antithetical symptoms, differed also in the velocity of their circulation. Of the several test methods that have been suggested for the determination of the circulation time, they chose the one that employs a 20 per cent solution of the sodium salt of dehydrocholic acid. They preferred this method (1) because it is rather simple, (2) because it is the least dangerous, and (3) because the diuresis induced by it has a therapeutic effect. The patient was advised to tell at once when a bitter taste appeared. The patient was lying quietly with the arm in the horizontal position, and 10 cc. of a 20 per cent solution of the sodium salt of dehydrocholic acid, diluted with 10 cc of a 30 per cent solution of dextrose was injected into the cubital vein. The injection was made in such a manner that 4 cc. of the solution was injected in ten seconds. Even if the bitter taste had already appeared, the

remaining quantity was always injected for therapeutic purposes. The time was determined that elapsed between the onset of the injection and the appearance of the bitter taste. Before the tests were made, the sensitivity of the taste was determined by means of graduated quinine and sugar solutions. The velocity of the circulation was tested in thirty-seven persons. It was observed that in patients with mitral stenosis the circulation time was slightly prolonged, while in those with aortic insufficiency it was considerably prolonged. To what extent the prolonged circulation time is due to a reduced velocity of the blood stream or to retarded secretion of fluid out of the blood stream cannot be determined with these experiments.

Causal Treatment of Poliomyelitis.—Barla-Szabo, after calling attention to the shortcomings of the specific serotherapy, enumerates the factors required of a causal therapy and shows that the virus of rabies meets some of these requirements in regard to poliomyelitis. Accordingly he decided to use the method employed for prophylactic vaccinations against hydrophobia in the treatment of poliomyelitis. The spinal cord of a rabbit infected with rabies served as material. He prepares the vaccination solution in the following manner. The infected material is ground in a sterile mortar and diluted with physiologic solution of sodium chloride. The substance thus prepared can be used for five or six days. The author begins the subcutaneous injections with a solution of 1:500 (0.1 Gm of brain substance and 50 cc of physiologic solution of sodium chloride). As a rule, ten subcutaneous injections are required. The first five are given daily and the later five at intervals of two days. The series of injections may be repeated after two weeks. The author employed this treatment in ten acute cases (from three to ten days after onset of the paralysis) and in seventeen subacute cases (from three to six weeks after onset of the paralysis). In the latter group, convalescent serum had not produced the desired results. Since in the small number of acute cases it is difficult to differentiate between spontaneous remission and remission as a result of treatment, he describes only the results obtained in the subacute cases. Two patients with diplegia and two others with diplegia and paralysis of the trunk began to walk again paretically after six days of treatment and the reflexes likewise returned after another five or six days. In seven other patients, of whom three had monoplegia, three diplegia and one diplegia and paralysis of the trunk cure was effected in from twenty to twenty-five days. The other six patients showed only slight improvement after twenty and twenty-two days, but after an additional twenty-five or thirty days two of them were cured, three were considerably improved and one was slightly improved.

Acute Rheumatism with Abdominal Symptoms.—Støren says that in the diagnosis of acute rheumatism with abdominal symptoms great importance attaches to the good intestinal peristalsis demonstrable on auscultation in spite of marked muscular resistance and tenderness. In the five cases reported, which were admitted as acute abdominal disorders, the two main types of abdominal pain in acute rheumatism were represented: one with paroxysmal pain with slight or no resistance, the other with marked resistance and tenderness. In the case

in which operation was performed there was an acute serous peritonitis. The cause of the abdominal symptoms described is thought probably to be an acute rheumatic peritoneal disturbance of varying intensity.

Acute Idiopathic Porphyria.—Opsahl asserts that the frequent negative results of the urine test in acute porphyria may be due to intermittent elimination and that the color of the urine is no indicator of the porphyrin content. In some cases Garrod's and in other cases Fischer's method prove unsatisfactory. For clinical use the following method for relative quantitative determination in porphyrinuria is presented. The urine is examined in mercury quartz light with Wood's filter for fluorescence. By the addition of iodine (1 drop of tincture of iodine to 5 cc of urine) the porphyrinogen possibly present, which does not fluoresce, is at once oxidized into fluorescing porphyrin. After the characteristic fluorescence has been found, the substance is identified according to Fischer's method.

Mesodermic Dystrophia (Marfan)—Arachnodactylia.—Christoffersen says that his typical case in an infant presents a combination not previously reported, mesodermic dystrophia and congenital pyloric stenosis. After operation for the stenosis a volvulus of the stomach developed, operative treatment was followed by uneventful recovery. Roentgen examination of the patient's cranium revealed a convexity of the orbits toward the foremost groove of the brain, an anomaly also seen in the mother. While lens luxation was not confirmed, there were indications of a luxation or a subluxation. Seven other cases of arachnodactylia on the maternal side of the patient's family are known.

Nongonitrous, Highly Toxic Form of Exophthalmic Goiter.—Gellerstedt and Norinder state that their case presented the clinical picture of a disturbance of the heart with gastro-intestinal disorders. Necropsy revealed a small firm thyroid. Histologic examination showed the thyroid to be abundantly vascularized, with strongly increased interstitial tissue, small lobuli and scanty lymphoid foci. The preponderantly small follicles were covered with a high cylindrical epithelium containing abundant fat and vacuoli. The colloid matter was lacking or remarkably scanty, consisting mainly of small homogeneous or granulated spheres and foamlike masses. The follicles also contained abundant desquamated epithelial cells and some red blood corpuscles. In many places the epithelium showed marked proliferation into the follicle lumen. The pronounced changes bore unmistakable characteristics of exophthalmic goiter. The atrophy and the tendency to fibrosis, however, appear rarely and only as the end stage of a long and grave exophthalmic disease.

REPEATED LUMBAR PUNCTURES OF SPINAL DRAINAGE

DIAGNOSTIC AND THERAPEUTIC VALUE IN TRAUMATIC AND ALLIED LESIONS OF THE
CENTRAL NERVOUS SYSTEM

WILLIAM SHARPE, M.D.

NEW YORK

The use of lumbar puncture as an important aid in the diagnosis of lesions of the central nervous system has become much more frequent within the past ten years, no longer is the test considered an "operation," deferred until the increasing severity of the patient's condition demands an accurate diagnosis and then often used as a last resort. Even today, however, in many hospitals lumbar puncture is employed only for diagnostic purposes and only in selected conditions, but the use of repeated lumbar punctures of spinal drainage in acute traumatic intracranial lesions is considered dangerous and radical.¹

During the past twenty years in this clinic, the use of diagnostic lumbar punctures has become progressively more frequent and earlier, as a part of the routine examination of any patient having complaints severe enough to warrant reference to a neurologic clinic.¹ As a diagnostic aid, there has been little or no criticism of its possible danger, except in subtentorial expanding lesions, and even in these conditions, if the lumbar puncture is properly performed, there is no danger of a serious complication. diagnostic lumbar punctures, and by all means therapeutic lumbar punctures, should always be performed with the manometric attachment, preferably the mercurial one, in this manner, the pressure of the cerebrospinal fluid can be accurately registered, and under no circumstances should an amount of cerebrospinal fluid be withdrawn to lower the pressure more than one half of the initial pressure. For diagnostic purposes alone, 2 cc of fluid is amply sufficient, but for therapeutic purposes, it is at times possible to withdraw slowly 20 cc and even more before the pressure is lowered to one half of the initial pressure. In these therapeutic cases, however, the free escape of the cerebrospinal fluid from the puncture needle, when no manometer is being used to estimate the pressure until the pressure is lowered to a point far below one half of the initial pressure, is attended by the well known definite danger of medullary complications of direct pressure by the foramen

magnum collar, as well as intracranial vascular alterations to the degree of spontaneous rupture of the arterioles themselves. Such lumbar punctures, especially without the use of the manometer, are not properly performed and therefore the possible resulting complications are not valid criticisms of the test itself. In this clinic in a period of twenty years, serious complications following lumbar punctures have occurred in only three patients, and in each case the test itself had not been properly performed—the cerebrospinal fluid having been allowed to escape freely from the needle without the manometric attachment and, therefore, no pressure reading having been made. In each of these earlier cases, necropsy disclosed that the rapid lowering of the high intracranial pressure had forced the median portion of the cerebellum into the foramen magnum. In no other patients have complications occurred during or following the lumbar puncture properly performed with the aid of the mercurial manometer.

The observations in this paper will be limited, first, to acute traumatic intracranial lesions in adults, children and the new-born, secondly, to acute traumatic lesions of the spinal cord, and, in the third place, to acute spontaneous intracranial hemorrhage of the subarachnoid type, so often diagnosed and confused clinically as cases of "apoplexy" within the internal capsule. Repeated lumbar punctures of spinal drainage to lessen the symptoms in selected conditions of diffuse purulent meningitis will merely be mentioned.

ACUTE TRAUMATIC INTRACRANIAL LESIONS

1 *In Adults*—As is now commonly recognized, the important factor in acute cases is not a fracture of the skull, whether of the vault or of the base, but an increased intracranial pressure, whether due to hemorrhage or to acute cerebral edema and increased amount of cerebrospinal fluid or to both. The presence of a fracture merely demonstrates that the cranial injury was sufficient to fracture the skull, and naturally fractures of the base are the more serious as indicative of a greater force at the time of the cranial impact in order to produce an indirect fracture, and, therefore, the much greater danger of associated complications of intracranial hemorrhage and acute cerebral edema. The presence of the fracture is frequently also of value in permitting free blood and excess cerebrospinal fluid to escape from the cranial cavity, a natural decompression and drainage thus results in lowering any marked intracranial pressure. However, in acute cases of cranial injury, if the intracranial pressure is markedly increased, this important fact should be determined as soon as possible after the patient has survived the period of initial shock.

The only accurate method of determining the presence of an increased intracranial pressure is by the

Read before the Section on Nervous and Mental Diseases at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 15, 1934.
¹ Sharpe, William. *Diagnosis and Treatment of Brain Injuries With and Without a Fracture of the Skull*. Philadelphia: J. B. Lippincott Company, 1920.

lumbar puncture. However, no prolonged examinations such as roentgenograms and lumbar puncture tests should be made until the patient has recovered from the initial shock of the injury, as such examinations merely prolong the shock. If the patient cannot recover from the shock with all the treatment directed to that end, surely neurologic examinations and tests will not lessen the shock, and they may even increase it.

If the diagnostic lumbar puncture reveals clear fluid under a normal pressure (from 6 to 8 mm of mercury), or if the pressure is only slightly increased to 10 mm and at the most to 12 mm, or if the fluid is merely blood tinged, a favorable prognosis may be given, the general condition of the patient being good and in the absence of serious internal bodily injuries. On the other hand, if the pressure of the cerebrospinal fluid is markedly increased to more than twice the normal (from 14 to 16 mm) and especially if it is bloody, the diagnostic lumbar puncture should be converted into a therapeutic one of spinal drainage by withdrawing slowly an amount of fluid to lower the pressure to one half of the initial pressure recorded. That is, if the initial pressure reads 20 mm, then only an amount of fluid should be withdrawn to lower the pressure to 10 mm and not below 10 mm. In this manner, there is no danger of medullary complications or of increasing intracranial hemorrhage. The latter fear, so often expressed in the literature, that lumbar punctures theoretically will permit greater intracranial hemorrhage to occur has not been observed in this clinic when a lumbar puncture has been properly performed with the aid of the manometer as previously described.

By use of the test tube rack, whereby the cerebrospinal fluid withdrawn at each puncture of spinal drainage is placed in a test tube and labeled consecutively with the date and the exact time attached, as the blood settles at the bottom of the tubes, the blood percentage can be estimated approximately and the lessening blood percentage of successive punctures is clearly demonstrated. Specimens may also be centrifugated or sent to the laboratory for accurate red blood cell counts but in this clinic the tube rack is considered a most impressive demonstration for the entire staff to observe the therapeutic value of repeated lumbar punctures of spinal drainage. Depending on the height of the increased intracranial pressure and the degree of percentage of blood in the cerebrospinal fluid, the frequency of the repeated lumbar punctures of spinal drainage will vary from one to two or three daily, and, in severe cases showing both high pressure and high blood percentage of the cerebrospinal fluid as many as four spinal drainage punctures each day (one every six hours) have given the best results. In these borderline cases, which are comparatively rare, if the high pressure and the blood percentage of the cerebrospinal fluid are not progressively lowered by the consecutive lumbar punctures, early cranial operation and drainage are indicated, before the patient reaches the serious period of medullary compression. To permit the intracranial hemorrhage to form a layer of supracortical clot during the period of expectant palliative treatment merely lessens the chances for a good end-result if the patient recovers and also makes operative cranial decompression and drainage imperative in the more severe cases.

In this clinic diagnostic lumbar punctures are part of the routine neurologic examination on all patients having acute head injuries of a severity warranting

their being brought to the hospital. Occasionally, the results of this test are surprising in cases of apparently trivial head injuries, which would be clinically diagnosed as simple concussion, contusions or laceration of the scalp without the aid of lumbar puncture. In this manner, cases of slowly increasing extradural hemorrhage have been immediately suspected by a definite rise of the pressure of clear cerebrospinal fluid, even in the absence of positive roentgenograms, and an early differential diagnosis of an increasing extradural hemorrhage from acute cerebral edema and excess cerebrospinal fluid is greatly aided by the amount of fluid withdrawn in order to lower the pressure to one half of the initial pressure recorded.

In the treatment of acute head injuries when the diagnostic lumbar puncture discloses clear or merely blood tinged cerebrospinal fluid under normal or only slightly increased pressure, the routine expectant palliative method, aided by dehydration of varying degrees is usually entirely satisfactory and the end-results are excellent. In these cases, even without lumbar punctures, the end-results would be the same, but the physician can never be certain in regard to the intracranial status without the diagnostic lumbar puncture. Also, if during the convalescence, symptoms and signs of an intracranial complication develop, then the results of this initial lumbar puncture will be of the greatest value for a comparison with those of a later test in order to determine accurately the progress of the intracranial condition. Only too frequently patients having apparently minor head injuries become gradually or suddenly worse during the first week, if the diagnostic lumbar puncture in the initial period has been negative, any marked rise of pressure, whether due to hemorrhage or to excess cerebrospinal fluid or to both, can be easily determined and treated accordingly.

In cases in which the initial diagnostic lumbar puncture discloses hemorrhage of a mild degree, or a moderately increased pressure of cerebral edema and an excess amount of cerebrospinal fluid, the patient will receive naturally more careful attention, especially dehydration will be added to the expectant palliative treatment, and the physician will be constantly on the lookout for the development of symptoms and signs of an increasing intracranial pressure. If these symptoms and signs appear, another lumbar puncture should be performed immediately to determine accurately the intracranial status.

In cases in which the initial lumbar puncture reveals a cerebrospinal fluid pressure of over 12 mm, whether or not the fluid is bloody in the experience of this clinic the expectant palliative treatment, aided by dehydration and the repeated lumbar punctures of spinal drainage, is eminently satisfactory in the vast majority of patients, so much so that the advisability of cranial operations of decompression and drainage has been greatly lessened. At the time of my last report on this subject in 1928,² the operative treatment of acute brain injuries was advised in 31 per cent of the cases, but now, up to Jan 1, 1934, this figure has been lowered to 26 per cent, the decrease in operative treatment being due chiefly to the more persistent use of repeated lumbar punctures of spinal drainage. Dehydration is of temporary value only in the less seriously injured patients having a moderate degree of cerebral edema and an excess of cerebrospinal fluid, especially in the absence of much blood in the cerebrospinal fluid.

2 Sharpe, William. *Neurosurgery: Principles, Diagnosis and Treatment*. Philadelphia: T. B. Lippincott Company, 1928.

Patients in whom the cerebrospinal fluid has a blood percentage higher than 10 should not be dehydrated for fear of hastening the coagulation of the free blood before it can be absorbed or drained and thus a layer of supracortical hemorrhagic clot of varying amount may be formed. There is a real danger that the organized residue of the blood clot may later produce cortical instability and even a partial blockage of the absorption of the cerebrospinal fluid. This causes a chronic condition of the "wet" brain type associated with persistent headaches, vertigo, early fatigue and changes of personality of the depressed or irritable type, and even convulsive seizures.

During the past twenty years in this clinic the total mortality of traumatic cranial lesions has been greatly lowered so that now it is less than 29 per cent and with the exclusion of those patients who are admitted to the hospital in a moribund condition and die within six hours from shock and internal injuries, the mortality is 18 per cent. Naturally, in the alcoholic, arteriosclerotic and nephritic type of patient, the prognosis must always be grave, since even apparently trivial bumps on the head may produce a severe degree of cerebral edema and the rapid development of a terminal medullary edema.

2 In Children—Fortunately, acute traumatic cerebral edema and an excess amount of cerebrospinal fluid are comparatively rare occurrences in children. There is also lessened danger of hemorrhage following head injuries, but any child with a cranial trauma of severity warranting admission to the hospital should, in my opinion, receive the careful examination suggested for adults and should be treated accordingly. In children under 12 years of age the expectant palliative treatment, aided by dehydration in selected cases, and repeated lumbar punctures of spinal drainage has been entirely satisfactory in 78 per cent, and in only 14 per cent has it been considered advisable to institute cranial drainage, in order to save the life and furnish the best possible chance for the ultimate recovery of function and normality. So often in the past, the end-results in patients having head injuries have been overlooked. The immediate saving of life is important, yet surely the efforts of the physician should be directed to include physical and especially mental recoveries, which are almost equally important socially.

3 In the New-Born—A tremendous advance has been made within recent years in the diagnosis and treatment of acute cerebral birth hemorrhage. The diagnosis is now no longer deferred for months after birth in order to await the appearance of signs of an intracranial lesions with delayed physical and mental development, such as inability to hold up the head, inability to sit up, increasing spasticity of the arms or legs and delayed speech. It is the present practice to perform diagnostic lumbar puncture immediately in a new-born baby whether or not it was born by an instrumental labor, if there is difficulty in nursing, refusal to nurse or abnormal stupor, especially in the presence of twitchings of the extremities or of the facial muscles, or even, in rare cases, convulsive seizures. If free blood is present in the cerebrospinal fluid, repeated lumbar punctures of spinal drainage are immediately instituted, just as in adults and children with head injuries, in order to permit the free blood to escape and thus avoid the great danger, not only of death but in some cases the even more tragic result of spasticity and retarded mentality. If the diagnostic lumbar punc-

ture reveals clear cerebrospinal fluid, the physician knows almost certainly that no intracranial hemorrhage has occurred and that the signs were most probably due to a temporary cerebral edema of varying degree.

In cases in which the cerebrospinal fluid is bloody, all treatment and not including the injection of mother's blood and other coagulants, should be directed toward aiding the natural absorption of the blood by draining as much of it as possible, and thus lessen its blood percentage, before it can coagulate to form the organization-residue of unabsorbed supracortical hemorrhage—the direct cause of future physical and mental cerebral signs. Once this fibrous organization residue has been formed about the supracortical veins in the sulci there results the serious probability of a partial blockage in the absorption of the normal cerebrospinal fluid through the stomas of exit in the walls of these supracortical veins and thus is presented the great danger of a chronic "wet" brain of the external hydrocephalic type associated with an increased intracranial pressure of varying degree. It is this later development of increased intracranial pressure and not a primary damage to the brain at the time of the acute hemorrhage at birth, that produces the chronic spastic paralysis and mental retardation in these patients. In a percentage of only one in sixteen cases in a large series has there been any pathologic evidence of a primary brain injury.

In acute cases of cerebral birth hemorrhage, the early diagnostic lumbar puncture disclosing bloody cerebrospinal fluid under varying degrees of increased pressure is converted into a therapeutic spinal drainage, owing to the presence of the open cranial fontanels, there is apparently no danger of producing medullary compression by permitting as much of the bloody cerebrospinal fluid to escape as will do so. In this clinic these therapeutic lumbar punctures are repeated every two hours until the blood percentage of the cerebrospinal fluid becomes less than 10, and then every six to twelve hours until the fluid is practically clear. The average number of spinal drainage punctures has been five in the milder cases and as many as twelve in the more serious ones with extensive hemorrhage under high intracranial pressure.

This method of spinal drainage has been eminently successful in over 80 per cent of the cases of acute cerebral birth hemorrhage, and in no case in this clinic has it been necessary to advise a cranial drainage of the hemorrhage during the past four years. This is also due to the fact that in the cases of massive gross hemorrhage such as follow rupture of the tentorium with cerebral and cerebellar laceration, the child is in a severe condition of shock and is usually moribund, so that no cranial operation nor even spinal drainage can be considered. It is, however, the milder cases that are so frequently overlooked in which the signs are often vague and indefinite, these cases should have the benefit of an early diagnostic lumbar puncture, and if bloody cerebrospinal fluid is revealed the repeated lumbar punctures of spinal drainage should be instituted immediately in the hope that all the hemorrhage can be drained the great danger of later physical and mental impairment being thus avoided. In many of these acute cases the patients are now apparently normal in every respect as the result of the outlined treatments, whereas, once the condition has been permitted to become chronic the most that can be expected from any known treatment is an improvement, never normality.

ACUTE TRAUMATIC LESIONS OF THE
SPINAL CORD

As in cranial injuries, the important factor in trauma of the spinal column is not the presence of fracture of the bony structure but rather the degree of involvement of nerve tissue, naturally, depressed fractures of the skull should be elevated soon after recovery from the initial shock. Likewise, direct bony compression of the spinal cord resulting from vertebral fracture dislocation should be relieved early, the one and only exception being the patient having such a marked fracture dislocation of the vertebrae that the spinal cord must have been irreparably and completely damaged by severance or extreme compression and therefore presenting a hopeless prognosis. Any operative procedure advised in these tragic cases merely discredits the operation and the surgeon.

Fortunately, however, the cases of direct bony compression of the spinal cord itself are comparatively rare—and the much more common condition in conjunction with fracture dislocation is the presence of partial or complete spinal canal block, whether due to a narrowing of the bony canal from the associated fracture dislocation, or, as frequently happens, to an edematous enlargement of the cord itself, to a degree that the canal may be entirely blocked at the site of the trauma. Just as in cranial injuries, the swollen edematous brain, together with hemorrhage and excess cerebrospinal fluid, may produce an increased intracranial pressure sufficient to cause medullary compression and even death of the patient so in traumatic lesions of the spinal cord the swollen edematous cord with varying degrees of subarachnoid hemorrhage may so fill and block the canal that a direct compression of the cord itself results in the clinical picture of acute transverse myelitis. Unless this extreme blockage is relieved at the earliest possible moment, many cord fibers may be considered permanently and hopelessly damaged.

An early diagnostic lumbar puncture to permit the use of the Queckenstedt test in order to determine the presence of canal block is absolutely essential in the rational treatment of patients having cord lesions. If no canal block is present, only the routine expectant palliative treatment with the usual orthopedic measures of immobilization and traction is indicated. If, however, a partial block of the canal is demonstrated by the Queckenstedt test, then, just as in traumatic intracranial lesions associated with increased pressure of hemorrhage, cerebral edema or excess cerebrospinal fluid, the diagnostic lumbar puncture is converted into a therapeutic one of spinal drainage, and as much bloody cerebrospinal fluid is drained as possible in the hope that the canal blockage can be lessened. In almost one half of our cases of partial canal block, in the absence of marked fracture dislocation to the degree of a definite kyphosis, spinal drainage of repeated lumbar punctures together with the usual measures of dehydration was sufficient to lessen and even remove the block, and when lumbar drainage failed, combined lumbar and cisternal punctures were entirely satisfactory. In no case of partial canal block in the absence of marked bony displacement was a spinal decompression of laminectomy necessary.

In cases of complete canal block, unless the vertebral fracture dislocation is so extensive that no amount of spinal and cisternal drainage could relieve the cord compression, the patients should be given the opportunity of having the canal block lessened by combined

lumbar-cisternal drainage of repeated punctures, if no immediate lessening of the canal block is demonstrated, an early laminectomy of direct spinal decompression and drainage should be performed to give the patient the greatest possible chance of improvement. The longer the delay, the greater the irreparable damage to nerve tissues by the continued compression. If the neurologist cannot state with certainty that the entire cord in cases of clinically acute traumatic transverse myelitis is irreparably damaged—and one cannot except when the roentgenograms reveal a vertebral malalignment of such a degree that the cord must have been destroyed—the patient, in my opinion should have the possible benefit of lumbar and cisternal drainage, and if that fails to lessen the canal block, then the advisability of an immediate decompression laminectomy should be considered. Patients having the clinical picture of complete transverse myelitis should not be condemned to a hopeless future without at least a determination of whether there is a canal block. Months later they may begin to move the toes, then the legs, and in rare cases they may even stand. Such partial improvement is not uncommon and clearly demonstrates the fact that the diagnosis of complete acute traumatic transverse myelitis cannot be made with certainty, because some of the cord fibers may not be irreparably damaged, and unless the canal block of vertebral malalignment is so extreme that the entire cord must have been destroyed, every opportunity should be given to the patient to obtain the greatest possible recovery of function.

ACUTE SPONTANEOUS INTRACRANIAL HEMOR-
RHAGE OF THE SO-CALLED APOPLEXY
SUBARACHNOID TYPE IN THE
ELDERLY

Careful histories and thorough physical and neurologic examinations are always most important and essential in the diagnosis and treatment of these patients, and, as an additional aid, the diagnostic lumbar puncture is of real value. It is not dangerous when properly performed in the manner described, for determining a definite diagnosis in the spontaneous cerebral accidents and vascular encephalopathies of the elderly. The latter vague generalizations of nomenclature are no longer satisfactory and only rarely is it impossible to classify with accuracy the character, as well as the localization and extent of the vascular lesion.

A diagnostic lumbar puncture that reveals clear cerebrospinal fluid is naturally not repeated, and not more than from 1 to 2 cc of cerebrospinal fluid is removed for laboratory examination. Clear cerebrospinal fluid immediately eliminates subarachnoid and ventricular hemorrhage, so that the lesion, if hemorrhagic, is localized most probably in the internal capsule or infrequently within the cerebral hemispheres. In the latter cases an increased intracranial pressure of varying degree is disclosed. In these cases of clear cerebrospinal fluid the possibilities also include arterial blockage of a thrombotic or embolic character, or simply a transient arteriospasm.

If, on the contrary, the cerebrospinal fluid at lumbar puncture is bloody, any form of arterial blockage is immediately excluded, and the diagnosis becomes limited to subarachnoid hemorrhage or to an extensive internal capsular hemorrhage that has ruptured into the ventricle, producing the most serious type of apoplexy, or to a massive cerebral hemorrhage that has ruptured into the subarachnoid spaces or into either lateral ventricle. Naturally, the history of the patient, including

the preexisting symptoms and signs the character of the onset of the acute illness, the examination of the heart, the blood pressure, the urinalysis and, of the greatest importance, a painstaking neurologic examination, in addition to the results of the lumbar puncture, will make possible the accurate diagnosis and localization of the lesion in almost all these cases of cerebral accidents.

With a diagnosis of subarachnoid hemorrhage, it has been the experience in this clinic that repeated lumbar punctures of spinal drainage not only permit a more rapid recovery of physical, mental and emotional functions of the patient but the degree of improvement may be so increased that the ultimate functional recovery may approximate normality.

During the past three years, nineteen patients have been admitted to the hospital with the final diagnosis of spontaneous subarachnoid hemorrhage of the elderly, and, without a diagnostic lumbar puncture, in seven of these patients the diagnosis would have been impossible. Just as in cases of cranial injuries, the diagnostic lumbar puncture should never be performed before the patient has recovered from the initial shock.

In patients having bloody cerebrospinal fluid when the diagnostic lumbar puncture is made, the pressure of the fluid was registered by the mercurial manometer and only enough bloody cerebrospinal fluid was removed to lower the pressure to one half of the initial pressure. Depending on the height of the increased pressure and on the degree of blood percentage in the cerebrospinal fluid, repeated lumbar punctures of spinal drainage were performed once a day in the milder cases and as many as six times a day in the more severe cases of extensive subarachnoid hemorrhage. Five therapeutic lumbar punctures have been done in the average case, the largest number in any one patient being eleven before the cerebrospinal fluid became straw colored and under normal pressure (from 6 to 8 mm of mercury). In no patient in this series of cases of simple subarachnoid hemorrhage has the condition become worse following the diagnostic lumbar puncture, and in each case the blood percentage has lessened in the successive therapeutic punctures of spinal drainage. In no patient in this series of cases of bloody cerebrospinal fluid has cranial drainage been considered either necessary or advisable, if spinal drainage is successful in eventually clearing the cerebrospinal fluid of blood, naturally cranial drainage is not indicated.

In the severe cases either of extensive internal capsular hemorrhage or of massive cerebral hemorrhage rupturing into the ventricles, the clinical picture was frequently one of profound shock at first, followed by the rapid onset of bilateral spasticity with rising temperature, so that not even a diagnostic lumbar puncture was to be considered, the mortality has been 100 per cent in these moribund patients. Fortunately, these most serious types of massive spontaneous hemorrhage are comparatively rare, as are the complete thromboses that have occurred in this clinic, the much more common types of so called apoplexy being the subarachnoid as described, with an excellent prognosis, and also the frequent cases of arteriospasm of only temporary impairment. The much described internal capsular hemorrhage of varying degree, and usually limited to a small area of the capsule itself, must not be confused with the described lesions, and usually a careful neurologic examination makes the differentiation possible. This is also true of the internal capsular thromboses of embolic origin.

SELECTED CASES OF DIFFUSE PURULENT MENINGITIS

As a last resort, repeated lumbar and cisternal punctures of spinal drainage may be used as a symptomatic treatment to relieve the persistent severe headache of high intracranial pressure. They may prove of real value, and occasionally the patient may recover with life. Such patients might have recovered without spinal drainage, and yet if the headaches are lessened and the patient's general condition is improved and no ill effects of spinal drainage are demonstrable, surely the advisability of this expectant palliative method of treatment should at least be considered. Naturally, the lumbar punctures should be properly performed, as in hemorrhagic intracranial lesions. The spinal mercurial manometer should always be used to estimate the initial pressure and only the amount of cerebrospinal fluid necessary to reduce the pressure one half and not lower than one half should be permitted to escape. If the spinal puncture is done in this manner there will be no danger of any medullary complication of foramen magnum compression or other unfavorable signs.

CONCLUSIONS

1 Lumbar puncture is an important diagnostic aid, and repeated lumbar punctures of spinal drainage are of therapeutic value in selected cases of traumatic and allied lesions of the central nervous system.

2 Diagnostic and therapeutic lumbar punctures are without danger when properly performed. The manometric attachment should always be used and only the amount of cerebrospinal fluid necessary to lower the pressure to one half of the initial pressure should be withdrawn.

3 In the most frequent subarachnoid type of traumatic intracranial and spinal hemorrhage, in adults, children and the new-born, and in the spontaneous subarachnoid "apoplexies" of the elderly, repeated lumbar punctures of spinal drainage not only reduced the mortality but give a higher percentage of recovery of function.

4 Therapeutic lumbar punctures of spinal drainage, combined with dehydration, have lessened by about 20 per cent the advisability of operative cranial drainage in head injuries in adults and by more than 50 per cent in the new-born.

129 Broad Street

ABSTRACT OF DISCUSSION

DR TEMPLE FAY, Philadelphia. In 1921 I introduced the method of "dehydration" as a therapeutic means of treating these acute traumatic cases. This year I had the opportunity of reviewing cases of head trauma covering a period of fourteen years. In this series about half of the cases were treated by the older methods. Therapeutic and diagnostic lumbar puncture was not done and surgical decompression was frequently resorted to. The mortality was 26 per cent. Following the advent of spinal drainage and dehydration, the mortality dropped so that in the latter half of the series it has never exceeded 18.2 per cent. This includes all patients that entered the hospital whether they lived three minutes or three weeks. After the third hour the mortality dropped sharply to 14 per cent where spinal drainage and dehydration were employed, and this mortality has been a consistent one over a period of ten years. I believe it can be said that there is ample clinical evidence in favor of the conservative methods described. Lumbar puncture should be undertaken with a full knowledge of the mechanisms involved so as to avoid the dangers Dr Sharpe has described. It is perfectly obvious that if the ventricular system is "open" and one reduces the fluid pressure so that there is an equalization of the loss of fluid from within

the brain ventricles and from without simultaneously, no actual mass movement of the brain in the direction of the foramen magnum will occur. If, however, lumbar puncture is not done until after the first day and the symptoms then require lumbar puncture, there may be real danger because of a tremendous mass edema of the brain with no free fluid spaces open, owing to a diffuse interstitial edema with cellular swelling. I believe that delayed lumbar puncture affords a very distinct danger of foraminal hernia. If one is going to adopt the method, it should be adopted sincerely from the very beginning either no lumbar puncture following the old school of thought, or frequent drainage as the best means of restoring oxygen and nutrition to the brain throughout a period of compression so that it may survive. Spinal drainage and reduction of intracranial pressure, after all, simply mean providing the additional space required by cerebral circulation during the period of swollen brain cells, hemorrhage, or an overaccumulation of spinal fluid. Spinal drainage, properly performed, has undoubtedly proved to be a valuable adjunct to treatment.

DR A. S. CRAWFORD, Detroit. Dr. Sharpe is one of the pioneers whose teachings and writings have stimulated the much wider use of lumbar puncture as a diagnostic and therapeutic means in treating these cases. As Dr. Fay has said, this has led to a clearer understanding of the conditions and has resulted, in a way, in greater conservatism, because it has helped to cure many cases without operation. In a careful analysis of more than 1,300 cases of definite craniocerebral injuries in the last eleven years, I found that during the last three years there has gradually been a tendency toward more conservatism in the use of lumbar puncture. At one time it was being done in nearly 50 per cent of the cases and now I find it necessary for diagnostic or therapeutic purposes in something over 10 per cent. Mortality rates have gradually become lower. I do not know that these two factors are necessarily interrelated, but I do know that as experience increases I am able to carry more cases through the critical period without the use of lumbar puncture. On the other hand, I feel that if there is any question of the diagnosis or prognosis a lumbar puncture should be done. If it is done carefully, as pointed out by the speaker, with fine needles and withdrawing slowly, there is very little risk. Of course, it must be realized that there is a great deal of risk in a certain type of case in which there is gross blood and blockage of the posterior fossa. With regard to treatment of hemorrhage in children, I have been able, by means of punctures, and particularly when I have found the localized blood to save some in whom spastic paraplegias would have developed. I remember two cases in which I put a needle in the cisterna and found gross blood. I was able to remove that blood and then go a little farther in and find clear spinal fluid showing that the hemorrhage was subdural but extra-arachnoid. These patients were going down hill rapidly and probably would have died, had the obstruction not been relieved. They were entirely cured. I think this is a subject which should be brought up periodically, because the reporting of experiences adds to the fund of knowledge and permits the application of better judgment.

DR NED R. SMITH, Tulsa, Okla. I wish to present a thought from the standpoint of the consulting neurologist who lives in a community in which there is no neurosurgeon. The traumatic head cases are for the most part seen by the general surgeon, and occasionally the neurologist is called in consultation. A month ago I heard a paper by an eminent neurosurgeon who deprecated the use of the lumbar puncture. At the end of that paper, I was convinced that he was quite sound in his point of view. At the end of Dr. Sharpe's paper, I am convinced that in his hands the lumbar puncture method and drainage has certain phases of distinct value. It seems to me that the weight of evidence thus far would point to the judicious use of the well known method of dehydration by intravenous and other types of medication, plus the always available diagnostic method of lumbar puncture if necessary.

DR PAUL C. BUCY, Chicago. I have always been a little perplexed by this difficulty about lumbar puncture or no lumbar puncture. The general surgeon has never outlined a standard method of treating all abdominal injuries. He doesn't set up a group of rules and say "We will always do this" and "We

will never do that." His treatment of the abdominal injury depends on what the intra-abdominal condition is. If the bladder is ruptured, he treats it one way, if the liver or spleen is ruptured, he treats it another way. In other words, he individualizes the treatment for the type of injury. The same thing is true of cranial injuries to a large extent. They are not all alike, in spite of the fact that they are classed more or less together under cranial or cerebral injury. What is needed is individualization of treatment and adaptation of treatment to the needs of the case. It seems to me just as illogical to say that we will always do a lumbar puncture as it is to say we will never do a lumbar puncture. I think that if our cases are studied and the necessary treatment applied in accordance with what exists in a given patient, the end results will be distinctly better. As to operation on head injuries, my experience with the subject is not as extensive as Dr. Sharpe's or Dr. Fay's. Nevertheless, if one excludes the cases of depressed fracture and intracranial hemorrhage, I have yet to see the patient who needs an operation, a decompression, if you like.

DR S. D. SWOPE, El Paso, Texas. The neurologist, the psychiatrist and the neurosurgeon must go hand in hand in work of this character. Few of us are able to combine those three qualities. They are so distinct and so characteristic in their requirements that one man can hardly complete all of them in the course of a lifetime. The diagnostic value of a lumbar puncture is always dependent on the careful examination of the patient from all sources. In the clinic with which I am affiliated, practically every psychiatric case is carefully examined by lumbar puncture. The prevalence of syphilitic infection alone would require that procedure in a community where the disease is probably more prevalent than in any other section of the United States. I would call attention to the importance of early decision in cases of birth injury. The average psychiatrist does not see the effect of birth injury until it is too late to accomplish anything in the way of specific results. The fact is that a baby born today and crying for the next three days in all probability has a cerebral injury, and that cerebral injury can be benefited only by immediate attention. The importance of lumbar puncture certainly depends on the amount of pressure, and all our lumbar punctures are regulated by mercury manometers, which will give us the nearest we can get to a natural result. I thoroughly concur in the suggestion that as a general rule the removal of 50 per cent of the pressure is amply sufficient, but there are times when conditions exist in which the removal must extend much further, and that also is a matter of judgment, which, after all, is the best armamentarium the physician has.

DR A. L. SHOOG, Kansas City, Mo. I agree with the author regarding the dangers, but if it is in the hands of a man who has had adequate experience, who has mechanical skill and a good knowledge of the central nervous system, the dangers may be reduced to nil, particularly if he selects his cases after careful neurologic examination. Regarding the type of manometer, I see no reason why one can't use either a mercury or a water manometer. Possibly in some cases the water manometer may be better.

DR ADRIAN VERBRUGGHE, Chicago. It is possible to divide skull fractures into certain categories and to suggest appropriate treatment for each category. First there is the type of patient who comes into the hospital with a head injury and is in severe shock and obviously about to die. I doubt whether it is wise to intervene in a case of this type except to treat the shock. Certainly one would not attempt to do a lumbar puncture in this type of case merely to find out whether the fluid is blood or not. There is a second type of patient who is admitted with a head injury, who may be slightly irrational but is relatively conscious and who will in all probability get better if he is left alone, and I cannot see any reason for not leaving him alone. There is another type of patient who is received into the hospital unconscious and whose level of consciousness and whose neurologic signs remain the same. One feels in these cases that anything which can be done to turn the tide in their favor should be done and for that reason an attempt is made to reduce the increased intracranial pressure. It seems that in these cases lumbar puncture, with halving of

the spinal manometric pressure, offers one of the principal indications of puncture. Thus, combined with the repeated intravenous injections of hypertonic dextrose solution, may be sufficient to turn the balance in favor of the patient. There is still another type of patient who does not require lumbar puncture—the patient who is draining cerebrospinal fluid from his ear or nose. He is performing a continuous lumbar puncture on himself. I must agree entirely with Dr. Bucy's unfavorable attitude toward decompression in head injury and certainly experience at the Cook County Hospital of Chicago confirms this. At this hospital decompression is very rarely performed for the purpose of relieving intracranial pressure. However, if an individual goes on for forty-eight hours or more in an unconscious state in spite of lumbar puncture and dehydration, it has been thought wise to perform decompression in some of these cases in order to afford an additional means of reducing the intracranial pressure.

DR. WILLIAM SHARPE, New York. There is no treatment that can be standardized. In the Pan-American Clinic we look on diagnostic puncture as simply a test just as one would test the reflexes or have roentgenograms taken, or any of the other tests in neurology. It is not a dangerous procedure in our experience, and I defy any neurologist to tell with any degree of certainty what the intracranial status is in these acute head injuries unless a lumbar puncture is performed. Many cases presenting merely contused scalps and no neurologic signs whatever have shown a blood percentage above 50 and it may be possible in some cases for the natural means of absorption to take care of all that blood so that no residue is left and the patient can regain his normality. I am thinking of normality in addition to recovery of life, and I think that in the past the profession has considered the patient who has been able to leave the hospital rather than the end result as to the normality of a patient able to earn his living and hold his job. I had that experience in looking over the records of four of the leading hospitals in New York over a ten-year period ten years after their discharge. Of the patients I could find and I found about 30 per cent of them 34 per cent plus were having symptoms and signs of their head injury. It was ascertained that in those patients still having symptoms and signs years after the head injury, frequently in the notes in the hospital I found "persistent headache, dizzy spells and increased blood pressure," which often was raised 10 or 15 points, and of course in that period twenty years ago, no lumbar puncture had ever been performed. It was the period when the ophthalmoscopic examination of the fundi was considered sufficient to determine an increased intracranial pressure in a traumatic lesion. Dr. Fay asked whether in dehydrating patients with bloody cerebrospinal fluid there would be any organic evidence later that possibly the dehydration did have some effect on the early coagulation of the free blood in the cerebrospinal fluid. I have been called to see patients when dehydration had been used and when there had been very bloody cerebrospinal fluid, and if operation was indicated on the fourth, fifth or sixth day the blood was found to be coagulated. Usually in these cases the blood does not coagulate for seven, eight or ten days ordinarily, so that it seemed to me that the dehydration did hasten the coagulation of the free blood and naturally, that is something one wishes to avoid for fear of a clot formation. The early accurate diagnosis by lumbar puncture in all of these cases is therefore important. I agree with Dr. Bucy in regard to operations for head injuries.

The Two Laws of Euclid.—Thus while modern physical science makes headlines for itself so fast there is difficulty even for experts to keep up with it. Sir James Jeans publicly acknowledges that photons, electrons and protons though their properties can be expressed mathematically, are really as meaningless as x , y and z to a child on its first lesson in algebra, and it has been admitted by someone else that the advance of physical knowledge is at present reduced to the extraction of one incomprehensible from another incomprehensible. Yet we are assured that the mathematical starting point for all this was Hero's synthesis of the two laws of Euclid which have merely been expanded by Newton, Einstein and Sulaiman to embrace all the activities of the universe.—Cushing, Harvey. The Humanizing of Science, *Science* 81 137 (Feb 8) 1935.

A study of the physiologic activity of the thyrotropic hormone of the anterior pituitary has shown that the stimulating effect of the hormone on the thyroid gland is only temporary and that retrogressive changes actually take place in spite of continued injections of the hormone. Korenchevsky¹ injected rats with a glycerol extract of the anterior pituitary for periods of from six to eleven weeks. A decrease in the weight of the thyroid gland was found, which averaged 17 per cent below the control weight. Siebert and Smith² and Verzar and Wahl³ noted that the rise in metabolic rate of guinea-pigs injected with thyrotropic hormone reached a peak by the tenth day and then returned to the normal level. The latter showed that a marked drop in basal metabolic rate occurred when the hormone was injected into thyroidectomized guinea-pigs. Houssay,

Fig. 1.—Effect of chronic injections of thyrotropic hormone on the metabolism of normal rats (average of eleven animals).

Biasotti and Mazzocco⁴ have reported that anterior pituitary extract causes a fall in the blood iodine of thyroidectomized dogs, which is the opposite of the response to the thyrotropic hormone in normal and hypophysectomized animals. Lee and Gagnon⁵ found that anterior pituitary extract caused a lowering of the metabolic rate of rats when injected for a prolonged period, the metabolic levels in some instances going as low as from 10 to 39 per cent below the preinjection value. Evans and Sarka⁶ obtained basal metabolic rates 18 per cent below the preinjection value in rats chronically treated with anterior pituitary extracts. Retrogressive changes in the thyroid gland of guinea-pigs and ducks treated over a long period with anterior

pituitary extracts have been noted by Aron,⁷ Loeb and Friedman,⁸ Schockaert,⁹ Thurston¹⁰ and Friedgood.¹¹

We have followed the changes in metabolic rate of a group of rats injected with large doses of a purified extract of thyrotropic hormone (fig 1). A rise in the metabolic rate occurs during the first week of injections, reaching a peak of plus 28 per cent, the metabolism then drops to the preinjection value by the second or

Fig 2—Normal thyroid gland of rat

third week and continues to fall, going as low as minus 29 per cent by the fifth week. This is the level of metabolism of the untreated hypophysectomized rat.¹² The microscopic appearance of the thyroid at this stage of treatment resembles that of the untreated hypophysectomized animal (figs 2 and 3). The pituitary glands of the animals injected with thyrotropic hormone for a long period of time give a negative response when tested for the presence of thyrotropic hormone, although they still contain the growth hormone.¹³

In studying the nature of this apparent resistance to the thyrotropic hormone, we have found that the serum of animals which have been injected for a long period of time with thyrotropic hormone contains a substance that is capable of inhibiting the action of thyrotropic hormone. The serum from these rats, when given in doses of from 0.5 to 1 cc twice daily for three days to hypophysectomized rats, prevented a rise in metabolic rate with amounts of thyrotropic hormone equal to 200 times the minimum effective dose (fig 4). A similar finding was obtained when normal rats and guinea-pigs were used as test animals.¹⁴

We have injected a horse with thyrotropic hormone for a period of four months. After one month the antithyrotropic substance was found to be present in the horse's serum. Extracts of the antithyrotropic serum of the horse have been prepared which, when given in doses of 0.4 cc, are capable of inhibiting the action of 100 units of thyrotropic hormone in the normal rat (fig 5). Larger amounts of the extract, up to 4 cc daily, not only inhibit the action of 100 units of thyrotropic hormone injected into normal rats but at the same time apparently inhibit the thyrotropic hor-

none of the animal's own pituitary gland, causing a fall in metabolic rate to minus 24 per cent, which is the metabolic rate of the hypophysectomized animal.

The antithyrotropic substance appears to be unstable. Boiling the extract at pH 5 for three minutes completely destroys the inhibitory substance. Furthermore, the extract has been found to lose a considerable degree of its potency when kept in sterile ampules in the refrigerator for two months. When kept at room temperature the potency was entirely lost after this time.

We have obtained the inhibitory substance in the serum of animals of different species that have been injected with thyrotropic hormone. In addition to the rat and horse, the guinea-pig, rabbit and dog have been studied. We have tested the blood from a small group of patients that have been given therapeutic injections of thyrotropic hormone, and we have evidence of the presence of the inhibitory substance in the serum of such cases. This finding is doubtless the explanation for the numerous negative reports on the clinical use of thyrotropic hormone. We have evidence also of the antithyrotropic hormone occurring spontaneously in the serum of certain patients exhibiting low basal metabolic rates.

The mechanism of the action of the antithyrotropic substance is not understood. It does not inhibit the action of thyroxine. Rats injected with thyrotropic hormone for periods of from forty to seventy days showed practically the same response to a given amount of thyroxine as normal animals. Furthermore, the giving of antithyrotropic serum in conjunction with thyroxine did not prevent a rise in metabolism. This would suggest that we are dealing with a substance quite different from diiodotyrosine, which Abelin¹⁵ has found to antagonize thyroxine, and also "Katchin" of Blum,¹⁶ which has the same property. Abelin and Wegelin¹⁷ showed that simultaneous injections of diiodotyrosine with anterior lobe preparations prevent the marked hyperplasia of the thyroid that is seen with

Fig 3—Involutional atrophy of thyroid after injection of thyrotropic hormone for two months. This resembles the thyroid of the hypophysectomized rat.

the latter alone. Anselmino and Hoffmann¹⁸ have prepared a lipid soluble extract of normal blood which also inhibits the action of thyroxine. Herold¹⁹ has shown that this lipid extract of normal blood prevents

hyperplasia of the thyroid in rats treated with small doses of thyrotropic hormone but that extract of blood from pregnancy and exophthalmic goiter²⁰ had no such action

It is to be hoped that a study of the combined action of the thyrotropic and antithyrotropic hormones on the thyroid gland may clear up some of the discrepancies between changes in function of the thyroid

Fig 4—Complete inhibition of thyrotropic hormone by the antithyrotropic serum tested on hypophysectomized rats

gland and the cellular activity. As is stated earlier in this paper, when the animal has built up its own antithyrotropic substance as a result of prolonged injections of thyrotropic hormone the thyroid gland undergoes hyperinvolution until it resembles somewhat the atrophic thyroid seen in the hypophysectomized animal. On the other hand in an attempt to find the amount of antithyrotropic hormone which would just inhibit the action of a definite amount of thyrotropic hormone we have found that a given amount of antithyrotropic hormone may be sufficient to prevent the rise in metabolic rate without inhibiting the production of hyperplasia of the thyroid by the thyrotropic hormone. Hypophysectomized rats that received both thyrotropic and antithyrotropic hormones for from seven to ten days showed hyperplastic changes at the end of this period,

Fig 5—Effect of antithyrotropic extract on the metabolism of normal rats treated with thyrotropic hormone

associated with a lowered metabolic rate, which was depressed in some instances to 38 per cent below normal (fig 6). It has been shown by a number of workers²¹ that the injection of thyrotropic hormone causes an outpouring of organic iodine from the thyroid gland. This is coincident with the appearance of vacuoles in the colloid of the gland and a rise in the

metabolic rate of the animal. These changes have been noted twenty-four hours after the first injection of the hormone. Hyperplastic changes in the thyroid appear later. One might possibly interpret the cellular changes in the thyroid as a compensatory effect in an attempt to replenish thyroid secretion that is being released from the gland. This would be in keeping with Marine's²² view that hyperplasia of the thyroid is due to a functional insufficiency of the gland.

In a large series of rats and guinea-pigs in which we have studied the morphologic changes of the thyroid coincident with changes in metabolic rate during treatment with thyrotropic hormone, we have found it difficult in many cases to correlate the microscopic appearance with the physiologic changes, as indicated by the metabolic rate. On the sixth day of injections of thyrotropic hormone in the rat one usually finds an increase in metabolic rate of 28 per cent and hyperplastic changes in the thyroid gland. On the tenth day of treatment the metabolic rate has dropped to plus 10 per cent, hyperplasia of the thyroid is still present, although evidence of involutionary changes may be seen (fig 7). Scattered throughout the gland are large

Fig 6—Hyperplasia of the thyroid of a hypophysectomized rat after seven daily injections of thyrotropic and antithyrotropic hormones. The metabolic rate was minus 26 per cent.

vesicles lined with a very flat epithelium and distended with a deeply staining colloid. By the fourteenth day of treatment a residual hyperplasia may still be present, but one usually finds the follicles lined with a flat epithelium and filled with dense colloid (fig 8), the metabolic rate at this time has returned to the normal level. However, one frequently finds exceptional cases, for instance, one animal with a metabolic rate of plus 41 per cent on the fourteenth day of injection showed marked involutional atrophy of the thyroid, in another case the metabolic rate had dropped to minus 18 per cent by the fourteenth day, while hyperplasia was still seen in the gland. Oehme, Paal and Kleime²³ have reported a similar observation in which there was present a very active thyroid following injections of thyrotropic hormone without an increase in metabolism.

A group of goitrous rats in which the thyroid morphology resembled the hyperplasia seen in exophthalmic goiter showed a subnormal metabolism, in some cases the rates were as low as minus 17 per cent. A severe

hyperthyroidism developed in these animals when thyrotropic hormone was given, the metabolic rates varied from plus 120 to plus 200 per cent. The animals that died, death being due apparently to thyrotoxicosis, showed beginning involutional atrophy of the thyroid.

Evidence has been gathered in the study of the physiologic properties of the thyrotropic hormone which suggests that the anterior pituitary may play an etiologic rôle in exophthalmic goiter. The finding of an antithyrotropic hormone brings in another factor that needs to be correlated with the present knowledge of thyroid disease. The injection of thyrotropic hormone produces a condition of hyperthyroidism in normal animals, which is only temporary because of the occurrence of large amounts of an inhibitory substance that antagonizes the action of the thyrotropic hormone. In exophthalmic goiter there is the condition that has been described as a "thyroid diarrhea," which causes the thyroid gland to pour out excessive amounts of thyroid hormone. Presumably the hyperplasia of the gland is an attempt to compensate for the rapid loss of its hormone. The characteristic course of the disease is a cyclic variation of acute exacerbations and remissions of hyperthyroid symptoms. The occurrence of an infection frequently is associated with a relapse of hyperthyroidism. Changes in the physiology of other endocrine organs, as in pregnancy, often coincide with a return of the hyperthyroidism. If one may assume that in the normal individual there is a balance between the thyrotropic hormone of the anterior pituitary and the inhibitory substance, one may then expect an upset of the balance to occur in clinical hyperthyroidism which is characterized either by an increase in the thyrotropic hormone or by a decrease in the inhibitory substance. An increase of the thyrotropic hormone probably occurs in those cases of acromegaly in which there is evidence of increased activity of the thyroid gland. In exophthalmic goiter in which no evidence of any objective changes in the anterior pituitary gland is found the mechanism for the production of the anti-

tropic substance. It is likely that a great many factors influence the balance of this mechanism of the stimulator and inhibitor and that there are also intrinsic factors in the thyroid gland which are responsible for the disturbance in its physiology.

One of us has postulated recently the theory of the principle of inverse response and of antihormones. Briefly stated, these theories are as follows: 1. The

Fig. 8—Involution of the thyroid of the rat after fourteen daily injections of thyrotropic hormone.

responsiveness of an individual to administered hormone varies inversely with the hormone content or production of the subject's own gland. 2. For each hormone there is an opposite an antagonistic or antihormone substance. 3. The absolute amount of a hormone and of its respective antagonist determines the degree of stability of the subject so far as this one particular endocrine function is concerned. The hormone antihormone complex may be regarded as a buffer system. Some individuals of a species may appear on superficial study to be normal as regards some endocrine function, yet they may have a decrease or an increase in the respective hormone buffer system, and this condition may be detected only when abnormal responses are obtained following the administration of hormone extracts. As has been mentioned previously, it follows that a supposedly hyperhormone state may in actuality be due not to an increase in the production of a specific hormone but to a decrease in the corresponding antagonistic substance. Also the converse condition—namely, a supposedly hypohormone state—may be due to an increased amount of antihormone. Endocrine dysfunction in general may be regarded as primarily a hormone antihormone imbalance.

These theories were enunciated largely on account of the clear-cut demonstration that we had obtained of the production, in readily detectable amounts in the serum of animals treated with thyrotropic hormone, of a substance that was antagonistic to the thyrotropic hormone. More recently, there have been made in our laboratory a number of observations that tend to support the theory as stated. Thus we have evidence of the existence of an antiketogenic substance,²⁴ of an anti-growth substance, of an antimaturity factor (pituitary) and of an antagonodotropic substance.²⁵ The active prin-

Fig. 7—Hyperplasia of thyroid of rat with beginning involution.

thyrotropic substance may possibly be defective. We have found that bacterial toxins increase the sensitivity of the experimental animal to thyrotropic hormone. It might be assumed that the toxin has interfered with the production of the inhibitory substance. One must consider also in the condition of the nontoxic parenchymatous goiter whether an upset in the balancing mechanism is present, with either a decrease of the thyrotropic hormone or an increase of the antithyro-

ciple in an antiserum produced as a result of long continued daily injections of hormone extracts may be regarded quite rightly as a possible antibody reaction to the administered extract (antigen). We prefer to think, however, of the antagonistic principles present in the serum of chronically treated animals as normal constituents of blood, the level of which has been increased by the treatment. We are encouraged further in this belief since we have found in the serum of certain human patients antithyrotropic substance and in other human cases an antimaturity substance. These patients had not been treated but there had occurred in them spontaneously a hormone imbalance resulting in the predominance of the respective antistubstance. Also we have been able to antagonize the estrogenic effect and in part the ovarian effect of a maturity hormone extract by another extract made from the pituitary glands of the same species. There is some evidence, therefore, that antagonistic hormones may be produced by the same gland. In fact in the case of the anterior pituitary we have evidence that the maturity or gonadotropic factor is associated with an antagonistic principle.

In the Welch lectures a few months ago a word of caution was given in regard to the indiscriminate use of glandular extracts—this in view of the danger of the production of a hyperantihormone state. We have now available and in use in our laboratory methods for assaying the blood serum for the presence of certain inhibitory substances. It appears to us that progress in clinical endocrinology will be more rapid as well as more certain if attention is for the time being diverted from treatment to a study of the blood of the patient so far as reliable methods are available.

THE ACTION OF IODINE IN THYROTOXICOSIS

WITH SPECIAL REFERENCE TO REFRACTORINESS

J. H. MEANS, M.D.

AND

JACOB LERMAN, M.D.
BOSTON

Eleven years has now elapsed since Plummer¹ introduced the use of iodine in the management of toxic goiter. During that entire period, iodine has been given as a routine in the Thyroid Clinic of the Massachusetts General Hospital and in some 575 cases its action has been made a matter of careful study. It is our purpose at the present time to evaluate this whole experience and to state the conclusions derived from it in the form that seems soundest to us today. We believe this a useful undertaking because it is evident that much confusion exists even now in the professional mind as to what iodine will and won't do in thyrotoxicosis.

A brief summary of the biologic facts of the problem is in order. First of all, it may be stated that, so far as is known, the sole function of the thyroid is the manufacture of thyroxine and that in toxic goiter this function is accelerated. The cause of the acceleration is obscure. Hyperfunctioning of adenomatous tissue is

a possibility, tissue that possesses the power to make the hormone but has escaped from whatever control governs the normal output of the gland. Following Plummer,² at one time the profession accepted as a fact that hyperfunctioning adenomas might occur in the thyroid. With the passing of time it has grown increasingly doubtful that they constitute an entity clinically separable from exophthalmic goiter. In the so-called toxic adenoma cases if one searches the non-adenomatous portion of the gland carefully enough, one usually can find areas of ordinary hyperplasia, also it appears that these patients usually respond to iodine as do those with typical exophthalmic goiter.

Two other explanations of hyperfunction are obvious. The gland cells may be whipped up to overactivity by some stimulus from without or they may because of an increased rate of removal of their product, hyperfunctionate to compensate. The known facts seem to us more consistent with the latter hypothesis. It has been shown, for example, that in toxic goiter the thyroid gland is poor in organic iodine, colloid and thyroxine³ and that the blood is abnormally rich in organic iodine and thyroxine⁴ and the urine in iodine⁵. Iodine, of course, is a necessary component of the thyroxine molecule but iodine exists in the body in other forms than as a part of this molecule. Nevertheless, the fall in thyroxine in the gland and the rise in the blood and the increased excretion of iodine in the urine suggest more rapid departure of the hormone from the gland, and the disappearance of colloid does the same, for it is in the form of iodothyroglobulin that thyroxine is stored in the acini. Thus emerges the concept of a leaking, or too porous gland that attempts to compensate for leakage of hormone by hyperplasia and hyperfunction.⁶ Another writer calls it "thyroid diarrhea."⁷ We believe also that the observed clinical facts are consistent with such a theory.

What these clinical facts are can be stated quite briefly. First, our entire experience confirms Plummer's original contention that iodine brings about a rapid amelioration of the symptoms of thyrotoxicosis in toxic goiter and, accompanying this a fall in basal metabolic rate. So constant and specific is this response that we have come to regard it as one of the cardinal manifestations of the disease. When it does not occur, we are always doubtful of the existence of thyrotoxicosis and search for some other explanation for the clinical picture. We make use of the specific response not only in treatment⁸ but for diagnosis.⁹ Its actual magnitude, so far as the metabolic side is concerned, is predictable with a fair degree of accuracy. It is in the neighborhood of 38 points of basal metabolic rate daily.

The preparation of iodine used is of no importance. Iodine is active in any form, provided the

From the Thyroid Clinic of the Massachusetts General Hospital. Read before the Section on Pharmacology and Therapeutics at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland June 13 1934.

1 Plummer H S. Results of Administering Iodine to Patients Having Exophthalmic Goiter. *J A M A* 80: 1955 (June 30) 1923.

minimum effective dose or more is given. At the present time we use 10 minims (0.6 cc) of saturated solution of potassium iodide once daily. This should be sufficient in any case.

The next important point is that the specific response will occur at any time during the course of the disease. It is not a feature merely of the onset of the malady. We have observed it taking place in characteristic form in a patient continuously thyrotoxic for eighteen years.

Chart 1 (case 1)—Basal metabolism chart in exophthalmic goiter showing exacerbation during iodine administration (pseudorefractoriness) and sudden upshoot on escape from iodine control. Readministration restored basal metabolic rate to level that had been reached when iodine was stopped. The iodine administration is shown in black, the arrow denotes operation. Attention is called to the fact that the time interval is in days to the right of the perpendicular line in months to the left.

Finally, it is our belief that iodine alters neither the duration nor the direction of progress of the disease. It merely, at any one moment, holds in abeyance a portion of its symptoms. This conception is not susceptible of proof, but our clinical experience makes us feel that its being correct is very probable.

One is next led to inquire in what way this specific response to iodine is brought about, and this question is intimately involved with that of refractoriness. It is the experience, doubtless, of all who give iodine to thyrotoxic patients that if the drug is continued the patients will often get worse in spite of it. Is this because the drug has become ineffectual and no longer capable of exerting an influence on thyroxine discharge or is it because the disease, entering a more severe stage, produces an intensification of symptoms in spite of a continued iodine control? One must bear in mind that control of symptoms by iodine is to be looked on as partial or relative, not total or absolute. Failure to grasp this fact is responsible for some of the existing differences of opinion about refractoriness.

Whether true refractoriness in the sense of cessation of drug action exists is difficult to determine. It has seemed to us that the behavior of the patient on stopping the drug is the chief source of evidence. Should a patient getting worse on iodine become refractory to iodine, one would expect that no great change in symptoms or direction of metabolic trend would occur on the omission of the drug. On the other hand, under the same circumstances should iodine be yet exerting some control, one would expect an intensification of the symptoms and an abruptly steeper upward trend of the basal metabolic rate. The patient, though getting worse on iodine, would get worse at a still faster pace on its omission, provided the drug was exerting some influence.

Scrutiny of our cases leads us to believe that the latter is what actually happens and to conclude therefore, that so-called refractoriness to iodine is apparent,

not real. The point is one of more than academic interest, because the therapeutic program depends on it. If a patient became truly refractory to iodine, the indication would be to stop the drug for a time and later resume its administration. If, on the other hand, there is no such thing as true refractoriness, iodine should be maintained steadily until thyroidectomy is performed. In 1917 Means and Aub¹⁰ called attention to the fact that a rising basal metabolic rate in toxic goiter indicates that surgery may be hazardous and that a rising metabolism constitutes a positive indication for the postponement of operation. This was in preiodine days. The principle, however, holds good now as well as then. Therefore the practical question comes up occasionally when one has a patient in the hospital, fully iodinated yet getting worse, of what shall be done with him. Shall he be taken off iodine or left on it? We believe he should be kept on. Nothing is gained by taking him off and he is allowed to run a greater risk of death from thyrotoxicosis by so doing. Our procedure would be to follow a policy of watchful waiting with iodination maintained. When a plateau had been reached, if not at too high a level, we should advise operation. Following such a course, we believe that the risk of toxic crisis or storm is minimized. Allowing escape from iodine control at a high level is definitely running the risk of storm.

Two cases will serve to illustrate these points.

CASE 1—Phyllis A., aged 19 years, with recurrent thyrotoxicosis (exophthalmic goiter), had a basal metabolic level in the neighborhood of plus 25. Under iodine it dropped slightly (chart 1), then rose again, although iodine was continued. One might say that she had become refractory to iodine. This is not true, however, for on the omission of iodine there is a very rapid rise in basal metabolic rate to a new high level of plus 60 and intensification of symptoms. On the readministration of iodine she returns to precisely the metabolic level which

Chart 2 (case 2)—Basal metabolism chart in exophthalmic goiter. At the left a positive diagnostic test with iodine is shown and then an exacerbation and remission, both occurring during maintained iodination. The iodine administration is shown in black.

she left on cessation of iodine. We have observed this sort of thing in other cases and believe that it represents the rule. Of course, ordinarily we do not omit iodine because, as already stated, we believe it undesirable from the patient's point of view to do so.

CASE 2—Beatrice H., aged 17 years, had a metabolic rate within the normal zone. There was a firm and somewhat

¹⁰ Means J. H. and Aub, J. C. A Study of Exophthalmic Goiter from the Point of View of the Basal Metabolism. J. A. M. A. 69: 13 (July, 7) 1917.

irregular thyroid with palpable thrill and bruit and very questionable thyrotoxic symptoms. There were no eye signs. Iodine was given for diagnostic purposes and as seen in chart 2 there was a prompt fall to a basal metabolic level in the neighborhood of minus 12 (from one of about plus 7). This is to be regarded as a positive test ruling in thyrotoxicosis. Subsequent events prove its trustworthiness. The patient was continued on iodine and in spite of it the basal metabolic rate continuously rose till it reached plus 40 and the symptomatology became typical. In other words a classic exophthalmic goiter was developing under our eyes in a fully iodinated patient. This might be interpreted as refractoriness but we believe, not correctly. The next chapter is that as iodine is further continued the metabolism again falls clear to a new low level of minus 23, and the symptoms improve. Had iodine been omitted in the middle of March and resumed early in April one would seemingly have had a perfect case for refractoriness. We believe, however, that the truth of the matter is that iodine has continuously exerted an effect in this case and that the curve indicates a spontaneous exacerbation and remission taking place in spite of iodine but at a lower level than would have obtained if no iodine had been used. The proof of this is the final event, namely, that when iodine is at last omitted, back comes the disease full-blown. This is another form of the diagnostic use of iodine—intensification of symptoms on omission instead of amelioration on giving the drug.

Addendum—After this paper was prepared certain additional data of importance were secured in case 2. The last metabolic rate determination shown in chart 2 was plus 27 per cent on June 6. For two months it fluctuated about plus 20 off iodine. August 4, iodine was given again. The metabolism promptly fell to minus 3 on August 11, and on August 12 the patient had a subtotal thyroidectomy. This added information confirms the opinion expressed in the paper that the rapid rise on cessation of iodine, beginning March 19, was due to escape from iodine control, and that the slower rise in the months of January, February and March, on iodine, was due to a natural intensification of the disease.

In 1931 our colleagues Drs W O Thompson and Phebe K Thompson¹¹ published the reports of a group of cases, some from the Massachusetts General Hospital, some from the Presbyterian Hospital in Chicago, which they believed showed refractoriness. We have studied these data rather carefully. In each case the omission of iodine is followed by a steeper upward trend of the metabolic curve. Therefore we believe that the interpretation of refractoriness is not entirely sound. In short, it seems to us that the thyrotoxic patient fails to respond to iodine only when he is already under its influence. On the omission of iodine a certain time, from two to three weeks perhaps, must elapse before a maximum response again can be had. This, we believe, is simply because it takes some such time for the effect of previous iodine to wear off or for the patient to escape fully from iodine control. He cannot respond to a second course of iodine until he has escaped from the influence of his first. The occasional apparent lack of response to iodine can be explained by the assumption that the drug was given at a time when the intensity of the intoxication was increasing. The effect of iodine under such circumstances might be merely to hold things level for a time.

It may be permissible to show again a diagram published some years ago,¹² which we still find consistent with what we observe clinically. It indicates simply that thyrotoxicosis runs its course, irrespective of iodine control, but that at any one time the intensity

of intoxication is less if the patient is under iodine control than if he is not. At any stage of the disease the effect of giving iodine will be to drop the intensity of thyrotoxicosis from the upper curve to the lower, and, of omitting it, the reverse.

How now, may one relate all this to the morbid physiology of the thyroid? We mentioned the appeal of the concept of a leaking gland. A plausible explanation of the action of iodine is that raising its concentration in the blood in part dams back the leak. The follicles fill up with colloid and the abnormally rapid escape of hormone is partly checked. When iodine is withdrawn, out it spills again.

The production of thyrotoxicosis by means of iodine, the so-called iod-Basedow of the Germans, is difficult to reconcile with such a theory. We are very doubtful however of the existence of iod-Basedow, having never ourselves seen any convincing evidence of it. Furthermore we have the word of one competent European investigator, Professor Dautrebande of Liege,¹³ that cases diagnosed iod-Basedow seen by him

Chart 3—Schematic representation of iodine relationships in toxic goiter. The curves represent the totality of thyrotoxicosis. The upper curve in each graph is the course that would be followed if no iodine was ever given; the lower the course that would be followed if iodine should be given throughout. The duration of the disease it will be noted is not affected by iodine nor is its direction of progress merely its intensity. The effect of giving iodine at any moment will be to drop the intoxication from the upper to the lower curve, as from a to b, that of omitting iodine the reverse, as from c to d. Graph II is added to indicate that the curve of full iodination and that of no iodination may not always be precisely parallel.

have responded to iodine in the usual manner. This certainly throws great doubt that iodine in the first place produced their thyrotoxicosis.

CONCLUSIONS

1 The clinical facts regarding iodine in thyrotoxicosis are that it produces an altogether characteristic and specific response, which consists in an amelioration of symptoms and a drop in metabolic rate. This response will occur at any stage of the disease.

2 It appears that the response has no relation to the duration or direction of progress of the disease but merely acts as a check on the intensity of its symptoms.

3 These clinical facts are consistent with the theory that in thyrotoxicosis the thyroid allows the escape of thyroxine to proceed at an excessive rate, to leak, in fact, and that the cells of the thyroid hyperfunction in consequence. Iodine, it is suggested, sets up a tem-

porary obstacle to this excessive outflow it checks the leakage of thyroxine from the gland. The known facts of iodine and thyroxine content of the gland, blood and urine are consistent with such a theory.

4 We believe that so-called refractoriness is apparent, not real. Thyrotoxic patients who are unaffected by iodine are those who are already fully iodinated.

5 We doubt the existence of so-called iod-Basedow.

6 The iodine response is valuable in the management of toxic goiter, both in treatment and in diagnosis, but its fundamental nature must be familiar if it is to be used successfully.

Although more is known about the thyroid than about any other gland of internal secretion, many important problems concerning its physiology and pharmacology remain unsolved. For example, very little is known about the mechanism of the action of thyroxine and more precise information should be obtained about the form or forms in which iodine occurs in the gland, the mechanism of the action of iodine in exophthalmic goiter and the relationship between the thyroid and other glands of internal secretion, notably the pituitary. It was with the idea of throwing some light on these problems that the present series of observations was undertaken.

THE RATE OF FORMATION OF THYROXINE

Boothby and his co-workers¹ and we ourselves² have shown that about 0.25 mg to 0.35 mg of thyroxine must be injected intravenously every day in order to maintain the basal metabolism of patients with marked myxedema at the normal level. In such patients there is little or no functioning thyroid tissue and this figure of about 0.3 mg (0.2 mg of iodine) daily is the nearest approach that can be made at present to the rate of formation of thyroxine or its equivalent by the normal thyroid gland. At this rate, in three score years and ten the thyroid of a normal individual would produce about 7.8 Gm of thyroxine. From the maintenance dose of thyroxine and the effect of 10 mg given intravenously in myxedematous man we have calculated that there are about 10 to 14 mg in the body of a normal individual outside of the thyroid gland, a figure almost

the same as that previously arrived at by Plummer³ and Boothby.⁴ If the figure for the rate of production of the thyroid hormone is approximately correct, then the iodine requirement of the normal thyroid may be about 0.2 mg a day and the amount of iodine supplied on the average to an individual in this country in the form of iodized salt (approximately 1.0 mg each day) is probably more than adequate for the prevention of simple goiter.

THE EFFECT OF THYROXINE

The intravenous administration of 10 mg of thyroxine produces about seven times as much effect when given to a patient whose basal metabolism is minus 40 per cent as when given to a patient with a normal level of metabolism.⁵ The duration of the effect both clinically and metabolically at the low level of metabolism is remarkable. Thus, 10 mg at this level raises the metabolism about 32 points on the average in from three to ten days and the effect on metabolism persists for from seventy to eighty days. Beginning about twenty-four to forty-eight hours after the injection is a period of intoxication, which lasts for from two to three weeks but is particularly marked during the first week and is characterized by aching and marked tenderness of the muscles, falling out of the hair and peeling of the skin. During the first few days there is often fever (the temperature sometimes rising as high as 104 F) occasionally nausea and rarely vomiting. The period of improvement which overlaps the period of intoxication begins a few days after the injection is given and gradually reaches a maximum about four to six weeks after the administration, when the metabolism has already fallen considerably. In other words the maximum clinical improvement following a single dose does not coincide with the maximum increase in metabolism. When the metabolism finally returns to its original level in from two to three months after treatment the patient is still alert and usually does not appear very myxedematous. Often the body weight is less than before the injection was given. The full blown picture of myxedema develops only after the metabolism has persisted at the level of minus 40 per cent for many weeks and in some instances for many months.

Because of the initial period of intoxication that follows the administration of a single large dose of thyroxine or of desiccated thyroid and the fact that improvement in a patient with myxedema occurs only slowly, the ideal method of treatment is to raise the metabolism gradually by slowly increasing doses until the minimum amount is being administered that will maintain the basal metabolism at the normal level. In this way unpleasant symptoms are avoided. In particular sudden changes in metabolism are to be avoided in patients with heart disease, notably those with angina pectoris. In patients with myxedema who are desperately ill there is great danger of death from large doses because of the period of intoxication and the slowness with which beneficial effects appear. They are unable to tolerate the sudden replacement of the very thing that their bodies lack. In the treatment of all patients with myxedema it should be remembered that adjust-

ment to any dose may require many months, and changes should be made slowly

IMPORTANCE OF THE PECULIAR CONFIGURATION OF THE THYROXINE MOLECULE

The marked reduction in the calorogenic activity of thyroxine produced by making slight changes in the molecule may be seen from chart 1. We have extended our previous observations⁶ and have noted that in a patient with myxedema the intravenous administration of 8.6 Gm of diiodothyrosine in sixteen injections over a period of eighteen days produced an increase in basal metabolism from minus 36 per cent to minus 26 per cent and a loss of 2.4 Kg. If this represents a true change, the effect per millimol was only about one ten thousandth that of thyroxine.

If a phenol group is added to the diiodothyrosine molecule with the formation of a diphenyl ether group, diiodothyronine is produced. This compound represents thyroxine with two atoms of iodine removed from the molecule. Diiodothyronine has a much greater calorogenic action than diiodothyrosine. Thus in one

to another without any clear-cut effect on metabolism. These observations with thyroxine and diiodothyronine show the importance of the iodine in the thyroxine molecule.

It is of interest to observe the effect of altering the amino group in the molecule. To do this, one of us (S. B. N.) has prepared N-acetyl thyroxine according to the method of Kendall and Osterberg.⁷ In this compound one of the hydrogen atoms of the amino group is replaced by an acetyl group. The acetyl group is comparatively stable and only slowly hydrolyzed. The intravenous administration of this substance in a dose of 31.5 mg produced only a slight but fairly prolonged increase in metabolism (from minus 41 to minus 35 per cent). When administered subcutaneously suspended in 10 per cent dextrose the effect was greater, 10.5 mg producing an increase in metabolism from minus 38 to minus 29 per cent in one patient and 21.0 mg an increase from minus 29 to minus 17 per cent in another. In both instances the effect was prolonged and in this respect resembled that of thyroxine. The prolonged calorogenic action of thyroxine and

Chart 1—Effect of alterations in the thyroxine molecule. All four iodine atoms, amino and diphenyl ether groups essential for maximum activity. Removal of two iodine atoms completely alters nature of metabolic response.

patient with myxedema 100 mg intravenously raised the metabolism from minus 36 per cent to minus 21 per cent and, in another, 150 mg raised it from minus 42 per cent to minus 22 per cent. This suggests that the presence of the diphenyl ether group is important. It is of interest to note the rather rapid return of the basal metabolism to the premedication level following the administration of diiodothyronine (seven and eight days respectively in two patients) compared with the slow return following the administration of thyroxine (from seventy to eighty days). Thus the removal of two atoms of iodine from the thyroxine molecule not only greatly reduces the efficacy of the compound in raising metabolism but also appears to alter the nature of the metabolic response.

If the remaining two atoms of iodine are removed to form thyronine or desiodothyronine, the calorogenic activity is still further reduced. We have given 228 mg intravenously over a period of five days to one patient with myxedema and 400 mg intravenously in two days

N-acetyl thyroxine (each containing four iodine atoms) compared with the much shorter action of diiodothyronine (containing only two) suggests that the prolonged effect of thyroxine may be dependent on the presence in the molecule of all four iodine atoms. It would also appear that substitution of one hydrogen atom of the amino group of thyroxine with a stable acetyl group yields a product (N-acetyl thyroxine) possessing very much less calorogenic activity.

These observations with various derivatives of thyroxine emphasize the importance of preserving the integrity of the thyroxine molecule if its maximum effect is to be produced.

DINITROPHENOL

Observations on the calorogenic action of alpha-dinitrophenol (1-2-4) ($C_6H_3(NO_2)_2OH$) have recently been reported by Cutting, Tainter and others⁸ in this country and by Magne,

Mayer, Plantefol and others⁹ in France According to Dodds and Pope,¹⁰ 3.5 dinitro-orthocresol is about three times as effective in the guinea-pig In chart 2 it may be seen that after a single large dose of dinitrophenol the effect on metabolism becomes maximum in a few hours, in comparison with from three to ten days after a single large dose of thyroxine After a single intravenous injection of 150 mg of diiodothyronine the effect becomes maximum in about two days, but, as in the case of dinitrophenol, the effect on metabolism disappears in a few days, although the effect is slightly more prolonged than that of dinitrophenol Unlike thyroxine, dinitrophenol appears to have about the same effect on metabolism regardless of the level before treatment There is only a slight effect on the pulse rate and a virtual absence of the initial period of intoxication that follows the administration of thyroxine In patients with myxedema in doses sufficient to raise the basal metabolism to normal there is little effect on body weight or clinical condition, although a few notice a slight increase in their sense of well being and slight muscle pain Thus a patient may continue to be myxedematous although the metabolism is raised from minus 40 per cent to normal When the rate is raised to about 50 per cent above normal there is some flushing of the

is about 63 per cent as great as its effect when given intravenously in the same form¹² It was thought that this well marked effect of an alkaline solution might be due to the formation of the disodium salt This salt was therefore made by one of us (S B N) according to the method of Kendall¹³ and had much less effect than an alkaline solution, possibly because of partial hydrolysis into sodium hydroxide and thyroxine¹⁴ Its effect was, indeed, about the same as that of the monosodium salt in crystalline form, which in turn was about 25 per cent as great as that of thyroxine given intravenously The free amino acid suspended in distilled water has only about one one hundred and fiftieth as much effect as thyroxine given intravenously

This augmentation by the action of alkali seen in the case of thyroxine is also noted in the case of a peptide of thyroxine¹⁵ prepared by proteolytic digestion of desiccated thyroid according to the method of Harington and Salter¹⁶ When suspended in distilled water and administered by mouth it produced only about 28 per

Chart 2—Dinitrophenol compared with diiodothyronine and thyroxine. Rapid rise and fall of metabolism after dinitrophenol somewhat similar to that after diiodothyronine but in marked contrast to slow rise and fall after thyroxine

skin, an increased sense of warmth and often the patient feels better, whereas an equal increase in metabolism produced by thyroxine would make the patient very uncomfortable The increased urinary excretion of nitrogen that follows the administration of thyroxine is said to be absent following the administration of dinitrophenol¹¹ From these observations it is apparent that the increased metabolism produced by thyroxine is different from that produced by dinitrophenol It is interesting that the latter exerts its marked calorogenic effect in spite of the fact that its molecule contains only one benzene ring and no iodine Although dinitrophenol may produce pharmacologic rather than physiologic effects, its marked action in the absence of thyroid function suggests that the basal metabolism may be altered by more than one mechanism

THE EFFECT OF ADMINISTERING THYROXINE IN VARIOUS FORMS BY MOUTH

Until recently it was thought that thyroxine had no effect by mouth, but it is now known that while it has only a slight effect as the free amino acid, it has a well marked effect when given in an alkaline solution, which

cent as much increase in basal metabolism as thyroxine given intravenously, or almost exactly the same effect as monosodium thyroxine This means that the peptide had nearly forty times as much effect per milligram of iodine as thyroxine given in the form of the free amino acid, suggesting that the combination of thyroxine with another amino acid in some way increases its absorption, possibly by facilitating the ease with which it forms a soluble salt in the small intestine When the peptide was given by mouth in alkaline solution, its effect was approximately three times as great as when it was given in suspension and slightly greater than that of thyroxine in alkaline solution In contrast to these

results with thyroxine and thyroxine peptide alkali did not have a clear-cut effect on the absorption of an acid-insoluble precipitate from a peptic digest¹⁷ of desiccated thyroid. Thus the effect of thyroxine was augmented most, that of the peptide less and that of the acid-insoluble precipitate not significantly. In other words as the complexity of the molecule increased the effect of alkali decreased.

IODINE IN RELATION TO THE CALORIGENIC ACTIVITY OF DESICCATED THYROID

Hunt and Seidell,¹⁸ Lerman and Salter¹⁹ and we ourselves² reported observations which suggested that the activity of desiccated thyroid was proportional to its total iodine content. On the other hand, Harrington and Randall²⁰ isolated diiodotyrosine from the thyroid by alkaline hydrolysis and by the action of proteolytic enzymes and concluded that at least 50 per cent of the total iodine was present in this form. Since diiodotyrosine possesses little calorogenic activity, there was a discrepancy between clinical observations on the one hand and chemical on the other. It is possible that the finding on the part of all three groups of investigators that activity is proportional to total iodine may have been a coincidence and that the problem may be more complex.

Our original conclusion was based on the observation that in each of two patients with myxedema the amounts of desiccated thyroid and of thyroxine that had to be given orally and intravenously respectively every day in order to hold the basal metabolism at normal contained the same total amounts of iodine. When we began to compare the effects of single large doses of the two substances we noticed that the effect of a certain lot of desiccated thyroid was on the average only 62 per cent as great as that of thyroxine given intravenously and that the ratio of the effects of the two substances varied greatly from patient to patient.²¹ Moreover comparison of the maintenance doses in the same patient showed that certain lots of sheep and beef thyroid had less effect than a lot of hog thyroid in doses containing the same total amounts of iodine.

The next logical step was to attempt to isolate from desiccated thyroid an iodine fraction that would possess most of the calorogenic activity. After digestion of desiccated thyroid with pepsin for seventy-two hours, most of the calorogenic activity is possessed by the acid insoluble portion which represents (in the lot used) only about 45 per cent of the total iodine. Data thus far collected suggest that, per milligram of iodine the effect of the acid-insoluble precipitate is greater than that of the desiccated thyroid from which it was prepared, but because of the disproportionate effects of increasing doses it is impossible at the present time to make quantitative comparisons.²²

The activity of a given amount of desiccated thyroid is usually slightly greater than that of the acid-insoluble portion derived from it, a discrepancy that may be explained by a slight calorogenic activity of the acid-soluble portion²³ which has been reported by Lerman and Salter²⁴ to possess no calorogenic activity. The curves denoting the changes in metabolism following single large doses of the acid-soluble portion appear to

be different from those for the acid insoluble portion, being characterized by a more rapid return to the level before treatment. Lerman and Salter²⁴ report that after digestion with pepsin for seventy-two hours desiccated thyroid loses about half of its activity and that the effect of the acid-insoluble portion is the same per milligram of iodine as that of the desiccated thyroid from which it is prepared. They therefore conclude that although diiodotyrosine is inert it "exerts calorogenic action when given in its natural chemical combination with thyroxine in the form of whole gland." It is impossible to state at the present time whether different methods of assay account for the differences in results.

EFFECT OF HEATING WITH ALKALI ON DESICCATED THYROID AND THYROXINE BEARING ON METHODS OF STANDARDIZATION OF DESICCATED THYROID

We have observed²² that, after heating with approximately normal sodium hydroxide on a water bath for four hours, desiccated thyroid loses more than two thirds of its calorogenic activity. No activity is lost if the mixtures are not heated. When thyroxine is heated with alkali in the same manner, its effect is not altered. Cameron and Carmichael,²⁵ on the basis of the rate of growth and hypertrophy of organs in rats, concluded that hydrolysis with sodium hydroxide destroyed at least two thirds of the activity of iodothyroglobulin. Regardless of the explanation of these observations, it becomes apparent at once that the method used by all investigators for isolation of the active principle from the thyroid, namely, hydrolysis with alkali, destroys most of the gland's activity. Indeed, the low yield of crystalline thyroxine from desiccated thyroid has always been one of the most serious handicaps to a systematic study of its properties and may be attributed either to destruction of thyroxine or to the presence of only a small quantity of iodine in the form of thyroxine to begin with.

The effect of heating desiccated thyroid with alkali has an important bearing on the suggestion advanced by Harrington and Randall²⁰ and by Gutman, Benedict, Baxter and Palmer²⁷ that for pharmaceutical purposes desiccated thyroid should be standardized in terms of thyroxine iodine rather than in terms of total organic iodine. Using guinea-pigs for assay, Gutman and his co-workers found calorogenic activity proportional to thyroxine rather than to total iodine. The assay methods of Hunt¹⁸ and Gudernatsch,²⁸ which depend on the effect of thyroid on the susceptibility of white mice to acetone and on the metamorphosis of tadpoles respectively, are certainly no more accurate than the total iodine method and have indeed led to the conclusion that activity is proportional to total iodine. Biologic assay on patients with myxedema is accurate but too time consuming to be practical, requiring as it does many months to standardize a single preparation. In many instances the determination of total organic iodine is probably satisfactory for clinical purposes. At present the glands used by several American manufacturers for the preparation of their desiccated thyroid

contain fairly high concentrations of iodine, and in normal glands with high iodine contents Gutman and his associates have found the relation between total organic iodine and thyroxine iodine to be fairly constant. They have also shown that the relationship between the two is much more constant in preparations of desiccated thyroid that conform to United States Pharmacopeia requirements than those which do not.²⁹ As long as the U. S. Pharmacopeia requirements are adhered to, similar results may frequently be obtained whether total organic iodine or thyroxine iodine is used for standardization. Nevertheless there is still room for a method of standardization that meets the most rigid chemical and metabolic standards. Such a method may depend on the determination of a certain fraction of the total iodine which possesses nearly all the calorogenic activity, but it must not destroy activity. Until such a method is adequately worked out and its reliability proved beyond question, it would probably be unwise for the United States Pharmacopeia to change its requirements

and 12 mg, although the exact figure is still to be determined. Other pertinent facts about the iodine reaction are that 1 The reaction may be reversible,³² i. e., the metabolism may rise and the severity of the disease increase during the administration of inadequate doses of iodine (from 0.75 to 3 mg daily) and show a well marked reduction during the immediate subsequent administration of much larger doses (250 mg daily). 2 The iodine must be administered at a certain minimum rate in order for the effect to be maximum, i. e., administration of 3 mg daily for fourteen days will not produce the same amount of reduction on the average as the administration of 6 mg daily for seven days. 3 Patients may be initially refractory to iodine or may become refractory after an initial response during its continuous administration.³³ 4 The same patient may show remissions and relapses in the disease when iodine is administered³⁴ continuously and when it is not administered at all. 5 Refractoriness to iodine may disappear after iodine has been omitted for four weeks.³⁵ 6 During the development of refractoriness, the minimum amount of iodine necessary to produce a maximum reduction in basal metabolism may increase.³⁶ 7 A dose of iodine which in itself is too small to cause a reduction in the rate of basal metabolism may interfere with the

Chart 3—Calorigenic action of anterior pituitary. Mild myxedema improved, nontoxic adenoma made toxic, exophthalmic goiter made worse.

Since no method has been demonstrated to yield with certainty the percentage of iodine present as thyroxine, the adoption of the thyroxine content as a method of standardization by the British pharmacopeia may seem a little premature. The need for an accurate method is obvious. It is hardly necessary to stress what Hunt has already pointed out, namely, that the statement that a patient has had a certain number of grains of thyroid in a given time is of little value.

IODINE REACTION

The precise nature of the iodine reaction³⁰ in exophthalmic goiter still remains a mystery. We have found that, in exophthalmic goiter in Boston, 6 mg of iodine a day is about the minimum amount that will produce a maximum reduction in basal metabolism,³¹ and in Chicago the amount is between 6

and 12 mg, although the exact figure is still to be determined. Other pertinent facts about the iodine reaction are that 1 The reaction may be reversible,³² i. e., the metabolism may rise and the severity of the disease increase during the administration of inadequate doses of iodine (from 0.75 to 3 mg daily) and show a well marked reduction during the immediate subsequent administration of much larger doses (250 mg daily). 2 The iodine must be administered at a certain minimum rate in order for the effect to be maximum, i. e., administration of 3 mg daily for fourteen days will not produce the same amount of reduction on the average as the administration of 6 mg daily for seven days. 3 Patients may be initially refractory to iodine or may become refractory after an initial response during its continuous administration.³³ 4 The same patient may show remissions and relapses in the disease when iodine is administered³⁴ continuously and when it is not administered at all. 5 Refractoriness to iodine may disappear after iodine has been omitted for four weeks.³⁵ 6 During the development of refractoriness, the minimum amount of iodine necessary to produce a maximum reduction in basal metabolism may increase.³⁶ 7 A dose of iodine which in itself is too small to cause a reduction in the rate of basal metabolism may interfere with the

festations of the iodine reaction in exophthalmic goiter are of great interest, but the mechanism of their production will be understood only when the nature of the chemical changes in the thyroid is known.

RELATION BETWEEN THE PITUITARY AND THE THYROID³⁷

Attempts to reproduce in man the effects that have been observed in animals during the administration of extracts of the anterior lobe of the pituitary have proved disappointing. Within the past six months we have had the good fortune to receive two extracts of the anterior lobe that produce an increase in metabolism in man. The extracts used were the growth hormone of E. R. Squibb & Sons and an extract of the anterior lobe manufactured under the name of Phylone by the Wilson Laboratories, Chicago.³⁸ We have administered these extracts subcutaneously to twenty-eight patients of various types. In eighteen of them the metabolism has shown an increase, which has always been temporary in spite of continued administration.

In ten of twelve patients who suffered from a moderate depression of the basal metabolism (minus 15 to minus 30 per cent) but whose clinical picture was not typical of hypothyroidism, the rate rose to normal or higher during the administration of the extract in association with clinical improvement. One of these patients has a pituitary tumor and another we believe to have Simmond's disease.

In two patients with marked myxedema no change was observed, although the extract was not given in sufficiently large doses to make this observation conclusive. In three patients with goiters and low basal metabolisms (minus 25 to minus 30 per cent) that we have attributed to an underfunction of the thyroid, the rate showed a well marked increase, and there was clinical improvement during administration of the extract. In one the goiter increased in size. In another the rate at which the basal metabolism dropped on omission of the extract was similar to the rate at which it drops from its point of maximum increase following a single large dose of thyroxine.

In three of six patients with normal basal metabolism and nontoxic goiters, and in one of four patients with normal basal metabolism but no goiter, the rate rose during the administration of the extract. In one of the patients with a nontoxic adenomatous goiter and a basal metabolism of minus 7 per cent the rate rose to plus 25 per cent in association with the development of tachycardia, weakness and increased sweating—clinical changes seen in mild cases of toxic adenoma.

In a patient with exophthalmic goiter, in association with an increase in basal metabolism from plus 28 per cent to plus 50 per cent there was marked increase in muscle weakness, nervousness, sweating and precordial pain, a slight increase in the pronouncement of the eyes and an increase in the size and firmness of the thyroid. During the injections a mild case of exophthalmic goiter became a moderately severe one. This observation must, of course, be confirmed in many other cases, but it coincides with the observations of Schockaert and Foster³⁹ and of Friedgood⁴⁰ in animals and

naturally raises the question of the role of the pituitary in exophthalmic goiter.

SUMMARY

It has been calculated that in a normal man the thyroid forms thyroxine or its equivalent at the rate of about 0.3 mg a day and that there are about from 10 to 14 mg in the body outside of the thyroid gland.

Following the intravenous administration of a single dose of 10 mg of thyroxine to a patient with myxedema there is a marked lag in the clinical improvement behind changes in the metabolic rate, the period of highest metabolism being characterized by intoxication and the period of falling metabolism by improvement.

Observations on the calorogenic action of diiodotyrosine, thyronine, diiodothyronine and N-acetyl thyroxine show that the amino group, the diphenyl ether group and all four iodine atoms are essential for the maximum effect of thyroxine. Of special interest is the rather rapid return of the metabolism to the level before treatment following a single dose of diiodothyronine (from seven to eight days respectively in two patients with rates of minus 35 per cent and minus 40 per cent) compared with the slow return following a single dose of thyroxine (from seventy to eighty days at a level of minus 40 per cent).

The increase in metabolism produced by dinitrophenol in myxedema, with little or no clinical improvement, suggests that there may be different types of altered metabolism that cannot be differentiated by changes in the rate of oxidation alone.

As the complexity of the molecule of various thyroxine compounds increases, the greater will be their absorption from the gastro-intestinal tract and hence the less the effect of alkali in augmenting the absorption.

As a result of digestion with pepsin, data have been obtained which suggest that nearly all the calorogenic activity of the whole gland is possessed by less than half of the total iodine (acid-insoluble precipitate). The acid-soluble portion does possess slight calorogenic activity and after a single large dose the metabolism appears to return to its level before treatment more rapidly than after an equal change produced by the acid-insoluble precipitate. This finding has an important bearing on the United States Pharmacopoeia method of standardizing desiccated thyroid by a determination of the total organic iodine.

After heating with approximately normal sodium hydroxide for four hours, desiccated thyroid loses more than two thirds of its calorogenic activity, whereas thyroxine is unaffected by the same treatment. This finding has an important bearing on the proposed standardization of desiccated thyroid by a determination of its thyroxine content.

The subcutaneous administration of extracts of the anterior lobe of the pituitary produced an increase in basal metabolism in eighteen of twenty-eight patients of various types, including two with hypopituitarism, ten with low basal metabolism of unknown cause, several with nontoxic goiters, including three patients with mild myxedema, and one case of exophthalmic goiter. During the injections in the patient with exophthalmic goiter, a mild case of the disease became a moderately severe one.

ABSTRACT OF DISCUSSION

ON PAPERS OF DRs COLLIP AND ANDERSON, MEANS
AND LERMAN, AND W O THOMPSON, PHEBE A.
THOMPSON, TAYLOR, NADLER AND DICKIE

DR GEORGE W CRILE, Cleveland We have listened to three very significant papers. The point I wish to make is that exophthalmic goiter is due to a pathologic physiology in the suprarenal-sympathetic system. If this is a fact, it is easy enough to put it to a test, and this my associates and I have done. In fourteen cases of typical primary hyperthyroidism and in twenty-four cases of recurrent hyperthyroidism, in each of which all the symptoms were present, we found that as the result of denervation of the suprarenal glands, without any operation at all on the thyroid gland, the disease as a whole disappeared. These results would suggest that the thyroid gland in and of itself is incapable of acquiring a hyperplasia or an excessive activity but that these are imposed on the thyroid gland most probably by the suprarenal-sympathetic system. A second interesting thing to me is a fact that bears on the pituitary. If it is a fact that division of the sympathetic system alone will completely arrest hyperthyroidism, these cases of basophilism of the pituitary should be controlled equally by denervation, because if the thyroid cannot acquire hyperplasia and develop exophthalmic goiter within itself or independently of the sympathetic nervous system I have a doubt whether the pituitary gland can acquire a basophilism by itself and independently of the sympathetic nervous system. We have tested this conception in a most interesting way. In one case presenting the whole symptom complex of polyglandular disease, denervation of the suprarenal glands cured the patient completely. All the symptoms disappeared. This would suggest that perhaps the possibility hasn't been sufficiently thought of that the sympathetic system itself governs the activity of all these glands, and that they, in turn, act on each other secondarily, just as the thyroid does on the body as a whole. Drs Means and Lerman spoke about the resistance of certain patients to iodine. It is obvious that if compound solution of iodine should be given to a patient with neurocirculatory asthenia or any form of hyperkinesism not due to increased thyroxine, that patient would not be benefited. Furthermore, if a patient in whom neurocirculatory asthenia or some other form of pathologic stimulation of the suprarenal-sympathetic system was present, but whose symptoms in some degree were produced by an increased activity of the thyroid gland, then that patient's symptoms could not be entirely relieved by compound solution of iodine, because it is effective only against thyroxine, and, when thyroxine is not the sole cause of the disease, compound solution of iodine cannot offer complete relief.

DR E C KENDALL, Rochester, Minn. In regard to the important paper of Drs Collip and Anderson, it will be of great interest to see whether they can produce an antihormone for all the rest of the hormones of the pituitary. It will be of still greater interest if they can produce an antihormone to insulin, to thyroxine, to the cortical hormone of the suprarenal, to epinephrine, and finally to ascorbic acid. If they do this, they are going to cause a great deal of trouble to present-day endocrinologists and clinicians and much more trouble to future medical students. I feel sure that the conclusions of Drs Means and Lerman are in accordance with what is known of the effect of iodine. It certainly is not through its effect on the tissues, its effect is on the thyroid gland alone and is therefore variable under different conditions. The paper of Dr Thompson and his co-workers was particularly interesting. Thyroxine was isolated twenty years ago this year. During the twenty years it has been found that there is no effect produced by desiccated thyroid that cannot be duplicated by pure crystalline thyroxine. I think it may safely be said that it is the sole active agent of the gland. I am inclined to believe that their conclusions concerning the acid insoluble fraction after enzyme action is best explained by small amounts of thyroxine that were not broken off by the enzyme action. When thyroxine is injected, a certain quantitative response is produced. If desiccated thyroid is administered, a certain quantitative response is produced. The response based on iodine in desiccated thyroid and iodine in thyroxine can therefore be

compared. In all cases there is more effect from desiccated thyroid than would be expected from its thyroxine content. Analysis of desiccated thyroid shows that, on the average, 25 per cent of the total iodine is in the form of thyroxine, but the effect produced by the administration of desiccated thyroid indicates the presence of about four times this amount of thyroxine. This raises the question: Is the thyroxine in desiccated thyroid more active than crystalline thyroxine because of an enhanced activity due to its peculiar form of combination within the protein or is there another explanation that is based on the fact that all of the crystalline thyroxine which is injected is not retained and utilized? I believe the simplest explanation is that only about 25 per cent of the crystalline thyroxine is retained in the body and held in the form that can function. The fact that the effect on the basal metabolic rate is in proportion to the total iodine in desiccated thyroid and not to 25 per cent of the total iodine is a mere coincidence.

DR HERRMANN L BRUNGART, Boston. Drs Collip and Anderson stated that increased activity of a hormone may be due, not to an increased amount or concentration of the hormone itself, but to a decrease in its antistimulant. Of interest in this connection are certain patients with the characteristic clinical features of thyrotoxicosis, the thyroid gland nevertheless appearing normal macroscopically and microscopically. I have observed two such patients this past year. Stricker reported a similar case in 1930 and other cases likewise have been observed. It is to be hoped that the work of Drs Collip and Anderson may eventually make possible a lowering of thyroid activity in patients with chronic heart disease, making complete thyroidectomy unnecessary. Dr Thompson and his co-workers referred to the differences in the metabolic actions of dinitrophenol and thyroid. My observations have been in accord with his. After removing the entire normal thyroid in patients with angina pectoris, feeding amounts of thyroid sufficient to bring the metabolic rate back to its preoperative level resulted in recurrence of attacks in five of six patients. Angina pectoris was precipitated after the same amount of effort that caused attacks before operation. When dinitrophenol was given instead of thyroid, the return to the preoperative metabolic level was not usually followed by a reappearance of angina. Thus, I believe, was due in large part to the fact that moderate metabolic rises after dinitrophenol do not entail a great increase in cardiac work. After dinitrophenol the increased oxygen is derived from each unit of blood, rather than, as in thyrotoxicosis, by an increase in the volume and velocity of blood flow. In using the term "basal metabolic rate" as an index of the amount of thyroid active principle within the body, one must recognize that other dissimilar agents may cause changes in the metabolic rate without necessarily influencing the work of the heart to the same degree. Measurements of the metabolic rate reflect only the calorific action of such substances. In the absence of dinitrophenol and certain unusual disease states, however, basal metabolic rate measurements still afford the best single index of either thyrotoxicosis with overactivity of the gland or of myxedema with underactivity of the gland.

DR A C IVY, Chicago. The suggestion of Drs Collip and Anderson that antihormones may be regarded as antibodies interests me because I have recently reported the experimental production of cretinism in rabbits by the injection of a thyrocytotoxic serum. This serum was prepared by injecting chickens with a saline extract of a rabbit's thyroid. Now having in mind their hypothesis concerning hormones and antihormones, I should like to ask how they would distinguish between a chalone and an antihormone. Until more is known about the nature of the material that Drs Collip and Anderson are injecting and the nature of the reactions that they are obtaining, I do not warm up to the term "antihormone" and have the same criticisms concerning it that Dr Kendall has pointed out. The point of this work, however, from a practical standpoint, is that when the physician injects an impure hormone product over a period of time he may observe an inhibitory or reversed reaction. Maybe the impurity in the product acts on the cells of the particular glands and destroys or inhibits them. Drs Means and Lerman have expressed skepticism concerning the clinical existence of iod-Basedow disease. Experimentally, I believe that there is a basis for thinking that it may occur. I have in mind

the work of Webster and his co-workers in which they produced diffuse hyperplasia of the thyroid by feeding certain types of cabbage. Given this marked diffuse hyperplasia, the administration of iodine to these rabbits caused marked increase in basal metabolism, and if large doses of iodine were given the animals died. I think this to be a good indication that a certain state of the thyroid may occur in which the administration of iodine, particularly in large doses, may produce toxic effects. In the same connection, I should like to ask Drs Means and Lerman this question, primarily for my own information. What happens to basal metabolism in those cases of colloid goiter in which, when iodine is given, a decrease in the size of the gland results? It is reported that in these cases histologic examination indicates that the colloid is thinned and then is absorbed from the acini into the blood. Theoretically, if the colloid in the gland is active the basal metabolic rate should go up, at least occasionally. The papers of Drs Means and Lerman and of Dr Thompson and his co-workers clear up a number of points in regard to the role of iodine in exophthalmic goiter, but the mechanism of "refractoriness to iodine" and some of the apparent paradoxical effects of iodine on the thyroid remain to be elucidated. Some physiologists used to say that the action of thyroid extract is due primarily to its stimulating action on metabolism and that if some other substance would stimulate metabolism to the same extent that thyroid extract does, this substance would have the same effects on the body that thyroid extract does. The work that has been done by Dr Thompson and others with dimethylphenol renders such a statement no longer tenable. That is, thyroid extract has specific effects on the body other than raising the metabolic rate.

DR. GEORGE M. CURTIS, Columbus, Ohio. In the work presented, the main evaluation of thyroid function has been based on the basal metabolic rate. My studies indicate that two other factors are as important, perhaps more so, in judging thyroid activity. I refer to the blood iodine and the urinary excretion of iodine. During the past ten years, and particularly since the work of von Fellenberg and his pupils Sturm and Lunde, considerable information has become available concerning the blood iodine and the daily loss of iodine in the urine. The blood iodine is an index of thyroid function. Following total thyroidectomy for cardiovascular disease, the blood iodine decreases to one-third its normal level. The two-third decrease corresponds to the alcohol insoluble fraction, which has been designated "organic" and which presumably contains the thyroid hormone. The loss of sugar in the urine is significant in evaluating the activity of the pancreatic islets. The loss of calcium in the urine is significant in evaluating parathyroid function. In the same manner the daily loss of iodine in the urine becomes of significance in evaluating thyroid activity. The thyroid hormone, as thyroxine or in whatever form it exists in the circulating blood, has a high iodine content. I have found an increased loss of iodine in the urine in patients with hyperthyroidism. The investigation of Drs Collip and Anderson has raised a new point of view concerning thyroid function, and particularly regarding the extrathyroidal factor of exophthalmic goiter. I would suggest three methods of determining the resultant changes in thyroid function: the basal metabolic rate, the blood iodine and the daily urinary loss of iodine. Drs Means and Lerman "doubt but do not deny" the existence of "iod-Basedow," that is, of iodine induced hyperthyroidism. This is in accord with my experience. It is not possible to produce readily "iod-Basedow." I have seen the blood iodine rise from 12 to more than 7,000 micrograms per hundred cubic centimeters subsequent to high iodine administration, without any evidence of hyperthyroidism. This is the common experience. There would appear to be an iodine deficiency factor in the genesis of hyperthyroidism. It is difficult to harmonize this with refractoriness to iodine. Further investigation is necessary. The demonstration of Dr Thompson and his co-workers of other than thyroxine iodine in the thyroid gland is in accord with my studies. I have even gone so far as to inquire whether iodine has another function in the human body, outside of the formation of the high iodine containing thyroid hormone.

DR. HAROLD T. HYMAN, New York. I would like to corroborate what Drs Means and Lerman have said about the therapeutics of iodides in the treatment of the diseases of the

thyroid gland. In 1920, with my late colleague Dr Kessel, I demonstrated the spontaneous course of exophthalmic goiter, showing that it was subject to exacerbations and remissions. It was our belief that the effect of the iodides would vary depending on whether the patient was treated in an up-hill phase of the disease or whether the patient was in a remission. Obviously the iodide effects would be more dramatic if the patient was seen during a remission. Obviously, too, if the patient received iodides during the exacerbation of the disease or an up-hill phase the amount of iodide effect might not be sufficient to overcome whatever it is that is the fundamental pathogenic factor in exophthalmic goiter. In consequence of this, one may have the spectacle of a therapeutic measure that is of value with the patient actually being worse for the time being. Under such circumstances the iodide should not be stopped but should be persisted in and the dosage increased. In a few instances in which patients were brought to us desperately ill with thyrotoxic storms, we had the temerity to treat them with thyroxine and in a few instances we thought we observed a genuinely specific effect. That point of view has been unpopular and has not been accepted even by our colleagues in our own institution, and for many years we have begged them to show us iod-Basedow when it appeared. Our experiences have been that the patients who had exacerbations of their disease when iodides were administered were either those who were caught in an up-hill phase or those in whom some extraneous factor was operating. I remember a woman who became very much worse while on iodide, and we discovered that the increase in her symptoms and her basal metabolic rate was due to the fact that next bed to her a patient was admitted with pneumonia. When her bed was moved to another corner of the room, her basal metabolic rate fell. The importance of these observations cannot be over-emphasized, because the majority of clinicians have been frightened about the use of iodine. In the first place, they were frightened because of the dictum that with adenomatous thyroid the iodide was of less value than in true hyperthyroidism. Then they were frightened into the belief that in simple goiter, true exophthalmic goiter might be produced by iodide administration. All of these fears should be put to rest permanently. The contribution of Drs Means and Lerman will be a great step forward in the intelligent use of iodides by the general practitioner.

DR. D. ROY McCULLAGH, Cleveland. Dr Crile has suggested that on account of the research on iodine which we have been doing in the biochemical department at the Cleveland Clinic, I might wish to comment on some of the papers. Most of the remarks that I would have attempted to make have already been made. As Dr Curtis has said, the test for blood iodine is now relatively simple and accurate and is unquestionably of valuable diagnostic assistance. I think, however, that Dr Curtis will agree that frequently the blood iodine, although elevated, does not seem to be as high as one would expect, as indicated by the general symptoms. This ultimately may have some important bearing on the explanation of the nature of exophthalmic goiter. I think possibly there may be substances other than thyroxine which alter metabolism in that condition. I should like to comment also on the startling reports from the group at Montreal. The natural thought, as Dr Ivy has mentioned, is that the observations reported by Drs Collip and Anderson might be due to immunologic phenomena. Certain observations have been reported elsewhere by Dr Collip that lead one to question this assumption. The final proof of whether or not there are real physiologic antihormones will be the isolation of these substances from normal animals or persons that have not been injected with hormone. The latter has already been reported and furnishes suggestive evidence that the antihormone theory is tenable. Our work at the clinic in collaboration with Dr Walsh is also suggestive. Working with the testicular hormone, we were unable to replace completely the functions of the testes when injecting this hormone. For this reason, we felt that there was a possibility that there was some other active internal secretion, and our work led us to postulate the existence of a chalone in the testes which apparently has the property of decreasing the size of the prostate, that is, the opposite property of the recognized testicular hormone. This, if true, would be an example and a truly physiologic example, of the conception that Drs Collip and Anderson have presented.

DR WALTER M. BOOTHBY, Rochester, Minn. I agree with Drs Means and Lerman that, so far as is known, no patient with exophthalmic goiter has ever been made worse by the proper use of iodine. The aggravation of the symptoms that frequently occurs when iodine is stopped or used intermittently must be differentiated and these patients cannot be considered as being made worse by its use. The use of iodine as a test for exophthalmic goiter has its limitations as well as its advantages and requires an accurate knowledge of the normal course of the disease as well as a thorough understanding of the effect of iodine. A fact usually not recognized is important in this connection, namely, the beneficial effect of iodine does not usually appear until ten days or two weeks after its administration has been started, and the beneficial effect thus produced lasts usually about the same length of time, the intermittent administration of iodine is bad and when used is frequently based on alternate weeks or alternate two weeks and therefore the effect of its action can easily be misinterpreted. Drs Means and Lerman say that they believe there is no such thing as "iod-Basedow." If the term is used to indicate that true Basedow's disease (true Grave's disease, true exophthalmic goiter), then their statement is correct. However, there is some evidence in this country and more evidence in the endemic goitrous districts of Europe that a certain number of patients with endemic goiter are rendered hyperthyroid by the administration of iodine. Plummer has always insisted that the hyperthyroidism of adenomatous goiter is a separate clinical entity and should be chiefly differentiated from true exophthalmic goiter—the failure to do so has prevented the earlier recognition of when iodine is and is not beneficial in the treatment of various thyroid conditions.

DR J. B. COLLIP, Montreal. I do not think it is the time and place to enter into a defense of the theory that we have suggested. We have presented certain facts which we feel will stand the test of further investigation, but our theoretical presentation may be wrong, it may be partially true or it may all be true. We were interested in this theory primarily as a basis for directing our own future work. Already, as Dr McCullagh has said, we have suggested evidence supporting certain phases of the theory. In regard to the use of the word "chalone," I do not think that the point of view which we have presented in our theoretical discussion is such that it is right to use the word "chalone" for the group of substances we are calling antihormones for lack of a better word. The terminology is in rather a bad shape, it is true. One may question rightly the use of the word "hormone" at all. A hormone, as it was thought of years ago, is supposed to act on the body as a whole. All of these pituitary principles which we have been dealing with lately act on another organ and there is, as Dr Kendall has pointed out in private discussion, a real point of difference between this group of pituitary principles and other hormones. I was interested in the remarks of Dr Curtis with regard to the possible use of iodine values of blood and urine as indicating the state of thyroid functioning, Dr McCullagh has now available a method that will make it quite simple apparently for a number of workers to apply this method.

DR J. H. MEANS, Boston. I doubted the existence of iod-Basedow, I don't deny its existence, but I have never seen it. What Dr Boothby says is important. The endemic in Switzerland is much more intense than anything known in this country. That may be the explanation. However, I was interested in Bern last summer to talk to Professor Dautrebande of Liege. He told me he also thought there was no such thing as iod-Basedow, in the sense the term is used today, namely, thyrotoxicosis produced by the giving of iodine. He said the cases he had seen, that had been called by his European brethren iod-Basedow, in his hands had responded to iodine therapy just like other cases of thyrotoxicosis. I am very grateful to Dr Curtis. I think his work is of extraordinary importance, and in following lines of the sort that he is lies the solution of some of these complicated problems about the thyroid. I was asked a question by Dr Ivy. I can't answer it. I haven't the faintest idea how colloid gets out of the thyroid. I have seen colloid being put into the follicles but I have been unable to discover that anybody knows how it gets out. I don't even know whether

it gets out, when iodine is given in colloid goiter. Of course, we have very little endemic goiter in Boston, so that I am not an authority on colloid goiter. But it does occur to me that if there is a reduction in size, and generally we don't get any reduction when we give iodine to people with sporadic colloid goiter, it may be because of differences in vascular engorgement. I didn't quite follow Dr Ivy's comment on the nature of the calorigenic action of thyroxine in relation to dimetrophenol. I think they are totally different. I think thyroxine has a calorigenic action, and a whole lot of other actions, which dimetrophenol does not possess, and that the effect of thyroxine on the body is peculiar to thyroxine and can be imitated by nothing else that is available today.

DR W. O. THOMPSON, Chicago. With regard to the acid soluble fraction which Dr Kendall said probably depended for its activity on thyroxine, I want to point out that we have not said what its activity depends on because we do not know. Dr Kendall has suggested that the discrepancy between the effect of thyroxine and desiccated thyroid may be more apparent than real because of relatively greater utilization of desiccated thyroid. He has wisely pointed out that one of the chief criticisms of our work is that we do not know how much of the active principles of the various substances administered was excreted unused. Nevertheless, I think that it has not yet been definitely proved that desiccated thyroid is utilized better than thyroxine, and in different patients the same dose of desiccated thyroid may produce very different effects. It is difficult to see how greater utilization of desiccated thyroid than of thyroxine would explain the great reduction in the calorigenic activity of the former as a result of heating with alkali.

MENINGOCOCCIC MENINGITIS

A NEW FORM OF THERAPY

ARCHIBALD L. HOYNE, M.D.
CHICAGO

Weisselbaum,¹ although not credited with priority² in observing the meningococcus, isolated and cultured it in 1887, thus he laid the foundation for the present etiologic conception of the disease. Jochmann³ initiated the clinical intrathecal use of an antiserum evaluated earlier by animal experimentation by Kolle and Wassermann.⁴

Flexner in 1907-1908⁵ reviewed the entire subject of meningococcic meningitis and as the result of extensive laboratory and clinical investigations demonstrated the value of an antimeningitis serum in the treatment of the disease. He attributed the benefits of the serum clinically to its antibacterial qualities.

This work has stood unquestioned, and very little change has been made in methods of preparation of serums, largely because the ability of the meningococcus to elaborate a toxin was not recognized. None of the more important articles on the subject, including the comprehensive reviews of Gordon⁶ in 1920 and Murray⁷ in 1929, admit the possibilities of the production of a

soluble toxin but do agree to the elaboration of an endotoxin Murray states that "no one has yet succeeded in demonstrating a soluble toxin in meningococcus cultures and all are ready to admit that such a toxin is not produced"

Efforts to associate any one type of the meningococcus or any particular strain with various epidemics have not been successful⁸ Clinicians generally agree that the present polyvalent antibacterial serums and methods of standardization are not wholly satisfactory, and this was well demonstrated in 1929 by Wright,⁹

TABLE 1—Reasons for Discarding Cases from Report

who showed in an outbreak observed by him that "a serum uniformly of the highest titer was not effective clinically" I have made somewhat similar observations in the contagious disease department of the Cook County Hospital

In an attempt to clarify the perplexities of the situation in regard to antimeningococcus serum, Ferry¹⁰ recently succeeded in demonstrating soluble exotoxins in bouillon filtrates of the four recognized Gordon types of the meningococcus These toxins, when injected individually into animals, developed specific antitoxins Convalescent serums were shown to possess neutralizing properties toward homologous soluble toxins Less extensive, but corroborative, work on the toxin¹¹ and antitoxin¹² has been recorded

Ferry concludes from his observations that the symptoms of meningococcic meningitis in laboratory animals (guinea-pig^{12a} monkey¹³ and rabbit¹⁴) result from a selective action of the toxin toward the cerebrospinal nervous system He found that animals receiving lethal doses of toxin intracisternally or lethal doses of viable culture intraspinally could be protected by intraperitoneal injections of antitoxin^{12b} but not by standard antimeningococcus serum,^{12c} and that animals immunized by sublethal intracisternal doses of toxin were resistant to lethal doses of live culture Ferry¹⁵ reports elsewhere in this issue that susceptible human beings

can be immunized against meningococcus toxin as revealed by subsequent skin test

The experimental antitoxin¹⁶ used in the present clinical study was of the same lots reported on by Ferry¹⁷ This antitoxin was prepared by injecting horses subcutaneously with increasing doses of the individual soluble toxins of the four types of meningococci¹⁰ The antitoxin property of the serum was determined by its ability to neutralize toxin, as shown by intradermal injection in susceptible human beings and by its ability to protect laboratory animals from lethal doses of toxin and culture Concentrated antitoxin was used in a few of the cases in my series This was prepared by standard concentration methods

Three hundred and seventy-two patients¹⁸ were discharged from the Cook County Hospital, Contagious Disease Department, from November 1932 to June 1934, with the diagnosis "epidemic meningitis" Of these, the records of 296 have been included in this report, the remaining being discarded for various reasons (table 1)

The 296 patients have been separated into a series of eighty-five receiving meningococcus antitoxin and a series of 211 receiving two well known standard brands of antimeningococcus serum The clinical diagnosis of all but forty cases was verified by smear or cultural identification of the specific micro-organism in the spinal fluid

Approximately every fifth to seventh patient received the experimental antitoxin during the early studies and every third patient during the latter half of the period Patients to receive the antitoxin were selected only by reason of their not having had previous antimeningococcus serum therapy It was the general impression among the hospital personnel that the patients treated with antitoxin were as a group more severely ill and had less hopeful prognosis on admission than those treated with the standard serums This was undoubtedly true during the latter half of the period as the efficacy of the antitoxin became more apparent The resident staff was specifically instructed not to withhold

TABLE 2—Comparison of Fatality Rates of Cases of Meningococcic Meningitis in Which Meningococcus Antitoxin and Standard Antimeningococcus Serum Were Given

Therapy	Number of Cases	All Deaths	Excluding Cases Fatal Within		
			24 Hours	36 Hours	48 Hours
Antitoxin	85	23.5%	17.5%	10.9%	9.0%

71 to 80	4	4	100.0%
Unknown	9	7	77.7%

of the antitoxin over antimeningococcus serum is apparent by comparison of the respective fatality rates of treated cases occurring at the same time, in the same hospital and under the same supervision. Consequently seasonal variations that might influence virulence of the meningococci are eliminated from the contrasted figures of table 1. Twenty deaths occurred in the series of eighty-five patients treated with meningococcus antitoxin, 117 deaths were recorded in the group of 211 patients treated with antimeningococcus serum. The percentage death rate was 23.5 for the antitoxin and 45.9 for the antiserum.

The age of patients included in the entire series ranged from 3 months to 80 years, averaging 22.7 years. The cases treated with antitoxin averaged 18.1 years and the antiserum-treated group 24.7 years. From a study of table 3, arranged in ten-year age groups and respective fatality rates, it appears that the antitoxin was given to the most favorable subjects.

Seventy-three antitoxin treated patients and 138 antiserum treated patients were 30 years of age or younger. These cases are arranged in ten-year age groups in table 4 and show that, regardless of age, the antitoxin resulted in a lower fatality rate. Above the age of 30 the ratio is more favorable, but the number of antitoxin treated cases is not sufficient to warrant comparison.

TABLE 4—Influence of Age on Antitoxin and Antiserum Therapy

Age	Cases		Deaths		Fatality Rates	
	Anti-toxin	Anti-serum	Anti-toxin	Anti-serum	Anti-toxin	Anti-serum
1 to 10	33	58	4	15	12.1%	26.1%
11 to 20	32	48	6	17	18.8%	35.4%
21 to 30	19	34	2	13	10.5%	38.2%
Totals	78	138	12	45	15.4%	32.6%

The period of hospitalization for all recovered patients averaged 17.3 days. It is notable that those receiving antitoxin averaged 16.2 days as compared to the antiserum treated group, which averaged 18.0 days per case. The average hospitalization time for 338 cases at the Cook County Hospital recently reported by Borovsky¹⁹ was twenty-three days.

Table 5 shows the cases discharged from Cook County Hospital diagnosed "epidemic meningitis,"

1915-1933 inclusive, with respective fatality rates. An improvement in the fatality rate during 1933 over other comparable years is seen. During 1933 in approximately 20 per cent of the cases reported the patients received antitoxin, and its effect on the death rate for that year is significant.

The average total amounts of experimental antitoxin and standard serum given to a patient who had recovered was approximately 161.7 cc and 123.5 cc respectively. The largest amount of antitoxin and standard serum administered in recovered patients was 360 cc for the former and 245 cc for the latter, and the smallest amount 75 and 40 cc respectively. Allergic manifestations occurred in 17.7 per cent of the antitoxin treated cases as compared to 28.9 per cent of those in which standard serum was given. In no instance did an ocular or auditory complication develop after the institution of antitoxin therapy, nevertheless, large doses of antitoxin were sometimes given in unsuccessful efforts to overcome such conditions when present at the time of the patient's admission.

Of eighty-five patients receiving the antitoxin, cisternal puncture was resorted to on only five occasions.

on as many patients. In only three instances and on the same number of patients were spinal drainage and treatment done twice during the same calendar day. The average number of lumbar punctures per case was not materially reduced except in a group of patients receiving antitoxin intravenously and intramuscularly.

In twenty-eight extremely severe but uncomplicated cases, 20 cc or more of meningococcus antitoxin was given intravenously or intramuscularly, of these patients eight died, with a fatality rate of 28.6 per cent. The twenty patients who recovered received an average of 173.6 cc of antitoxin per patient, of which an average of 58.5 cc was given intravenously and/or intramuscularly and 115.1 cc per patient intraspinally. The period of hospitalization for this group averaged 13.6 days per case as compared to 17.5 days for the combined series.

SUMMARY

My experiences during the past one and one-half years seem to justify certain conclusions regarding the treatment of meningococcic meningitis. Meningococcus antitoxin has reduced by approximately 50 per cent the deaths from meningococcic meningitis at Cook County Hospital.

For many years it has been customary in the Contagious Disease Department of the Cook County

¹⁹ Borovsky, M. P. Clinical Study of Meningococcus Meningitis. Illinois M. J. 64: 532 (Dec.) 1933.

Hospital to administer antimeningococcus serum intrathecally not oftener than once in twenty-four hours. This plan was adhered to when meningococcus antitoxin was given. Lumbar punctures when made every twelve hours or at eight hour intervals, as sometimes recommended, are extremely disturbing to many patients and seem to be of no added value in lowering the fatality rate.

Although cisternal punctures are much more easily performed by one with experience than lumbar punctures and are often preferred by the patient, this procedure should not be encouraged in a public hospital in which interns and residents are frequently changed. I do not believe that cisternal puncture is necessary in the treatment of meningococcic meningitis in order to secure the most efficient results. It is not essential to adopt this route for the purpose either of drainage or of administration of serum except in case of block in the spinal canal. In no instance among the entire series of 372 patients was an intraventricular puncture required.

In the brief report²⁰ of a meningococcic meningitis patient treated at Cook County Hospital in 1918, the value of giving antimeningococcus serum intravenously was emphasized. Since that time it has been customary to resort to intravenous serum therapy for all adult meningococcic meningitis patients admitted to my service. The value of this procedure is still more apparent when antitoxin instead of antimeningococcus serum is the remedy. As our experience with the antitoxin increased, larger and larger amounts of meningococcus antitoxin were given intravenously. The dose ranged from 20 cc among the earlier cases up to 100 cc and more during recent months. These large amounts of antitoxin intravenously explain chiefly the greater average dose of antitoxin as compared with antimeningococcus serum. On the other hand, the greater the quantity of antitoxin given intravenously, the smaller the average amount required for intrathecal injection. The most outstanding feature of intravenous and intramuscular antitoxin treatment is the prompt response of the infection and a more than 20 per cent reduction in the period of hospitalization. In fact, it is my impression that eventually it may be regarded as entirely unnecessary to administer any serum intrathecally if sufficient antitoxin is injected intravenously. Under such circumstances lumbar puncture would be done only for the purpose of diagnosis and for drainage.

A problem is now under way to compare the efficacy of intravenous and intramuscular methods of administration supplementing intrathecal antitoxin. One young woman with a fulminating type of meningococcemia whose child died of meningococcic meningitis was treated only by large doses of antitoxin intravenously. Meningeal infection did not progress and she was discharged completely recovered on the seventh hospital day.

For the treatment of meningococcic meningitis with meningococcus antitoxin the following plan may be followed:

1 Intravenously from 60 to 100 cc. of the antitoxin is administered in from 120 to 200 cc. or more, respectively, of physiologic solution of sodium chloride or 10 per cent dextrose solution. The smaller amount may suffice for a child, the larger quantity for an adult.

This form of treatment may be repeated daily if the condition of the patient seems to require it. As a rule, one large dose intravenously when therapy is started will prove sufficient by this route.

2 Intraspinally the amount of antitoxin, undiluted, and given by the gravity method, will be governed by the volume of spinal fluid withdrawn. Usually the quantity of antitoxin administered should be less than the amount of spinal fluid released. The initial dose of antitoxin intraspinally will usually vary from 20 to 40 cc. Daily punctures should be made until the fluid is clear and free from organisms. At such a time the cell count of the spinal fluid will generally be less than 100.

3 Intramuscular administration of serum in an initial dose of from 30 to 60 cc is of value, but because of the serious nature of the disease the intravenous route is to be preferred.²¹

ACTIVE IMMUNIZATION WITH MENINGOCOCCUS TOXIN

N S FERRY, MD

DETROIT

AND

A H STEELE, MD

NORTHVILLE, MICH

In 1931 it was shown² that bouillon filtrates of young cultures of the four recognized Gordon types of the meningococcus contain soluble or extracellular toxins specific to the individual types, as well as a toxin common to all types, and that animals injected with these toxins develop antitoxins specific to their homologous toxins and an antitoxin more or less common to all types (a clinical study of this antitoxin will be found elsewhere in this issue of *THE JOURNAL*²²).

It was also shown that a certain proportion (about 50 per cent) of children are susceptible to one or more of these toxins, following intracutaneous injections of the diluted toxin, the test being carried out in a manner similar to the Schick and Dick tests for susceptibility to diphtheria and scarlet fever, respectively.

It was later demonstrated³ that this soluble toxin has a specific action on the central nervous system of laboratory animals, especially the monkey, and that when injected intracisternally it produces symptoms similar in nature and approaching in severity those

21 Since the preparation of this paper, twenty three additional patients with meningococcic meningitis have been treated in the contagious disease department of the Cook County Hospital. Six of this number received standard makes of antimeningococcus serum. The other seventeen were treated with the experimental meningococcus antitoxin. In the first group three of the six who received the standard anti-meningococcus serum died. The youngest of the three who died was 7 months old and the eldest 5 1/2 years. Of the three who recovered one was treated with the experimental antitoxin after he failed to respond to the standard serum. In the antitoxin group of seventeen there was but one death—that of a man aged 38, with a history of alcoholism who died the third day after admission. Of the remaining sixteen who recovered the youngest was 5 months of age and the eldest 35 years. By adding the seventeen antitoxin cases mentioned here to the eighty five previously analyzed it is found that of the 102 patients with meningococcic meningitis who were treated with experimental antitoxin there were twenty-one deaths, or a fatality rate for the entire series of 20.5 per cent.

resulting from intraspinal inoculations of live meningococci. It was discovered at that time that recovery from previous intracisternal injections of the toxin induced a state of active immunity in those animals against an intraspinal inoculation of a fatal dose of live organisms, similar to that immunity, following recovery from the disease, shown previously in one of these studies.⁴

The meningococcus, therefore, produces a true soluble toxin that will stimulate an active immunity in laboratory animals against the live organism as well as its toxin.

The present work was carried out to determine whether active immunity against the toxin, or at least the skin test dose of toxin, could be induced in man by a series of subcutaneous injections of the undiluted toxin. Accordingly, a large number of children, ranging from 12 to 18 years of age, were skin tested and those showing positive reactions to one skin test dose of the toxin were injected subcutaneously with the undiluted material.⁵

The method of procedure was as follows. A toxin was prepared from type I-III culture of the meningococcus and diluted according to a standard toxin, so that 0.1 cc contained a skin test dose. This dose was previously determined to be that amount of toxin which, when injected intracutaneously in a dose of 0.1

being 0.1 cc, 0.5 cc, 1 cc and 1.5 cc, equivalent to 13,500 skin test doses. As the immunizing toxin contained approximately an equal amount of each individual toxin, it is evident that the toxin homologous to the test material represented but from one fourth to one third of the whole, depending on the amount of toxin common to all types present in the mixture. In other words, the children injected with the four doses did not receive more than the equivalent of 4,000 skin test doses of any one of the type toxins.

At the end of eight weeks all children were retested with a skin test dose of toxin to determine the number of those who had become immune to the toxin.

Three types of reaction to the injection of undiluted toxin were observed. First, local reactions. About 50 per cent of the children showed local reactions mostly of a mild character, which caused the child to complain only of slight soreness or stiffness of the arm. Second, general or systemic reactions. Approximately 10 per cent of the group exhibited mild systemic reactions, following the second or third injection, the symptoms of which were headache, dizziness, gastro-intestinal upsets and a slight elevation of temperature. These reactions invariably disappeared within eighteen hours. Third, allergic reactions. In four instances immediate reactions after the second injection, consisting of generalized urticaria and, in one case, abdominal cramps accompanied by mild prostration. These symptoms were promptly controlled by an adequate dose of epinephrine. Further injections were discontinued in these cases as a precautionary measure.

Out of the 285 positive reactors fifty-three, for one reason or another, did not receive full treatment and were not retested.

Of the 232 who were given the full number of injections and were retested, including both groups, 155, or 66.8 per cent, gave negative reactions on retesting. Had the amount of toxin been increased, or had only the homologous toxin been given, the percentage of negative reactors would undoubtedly have been higher.

COMMENT

This work has demonstrated two facts: first, that certain individuals who are susceptible to the skin test dose of meningococcus toxin can be made immune to this dose of toxin by at least three subcutaneous injections of the undiluted toxin in graduated doses, and, second, that this immunity can be produced against the toxin of one type by injections of a mixture of toxins of all types.

While the results of these tests indicate certain facts in regard to the stimulation of active immunity in man against meningococcus toxin, they do not necessarily signify that an immunity against the organism can be produced at the same time, although such a condition is true of some soluble toxins and it is not unreasonable to expect the same of this toxin. This method of immunization, however, does suggest a possible means of active protection against the disease itself and is worthy of consideration and further study, especially since it was shown in a previous paper in this series that active immunity against infection with the virulent meningococcus can be stimulated in laboratory animals following prophylactic injections of this toxin. The answer to this question, while of great importance, must of necessity be deferred until such a time as more conclusive clinical data are available.

cc into an individual susceptible to the toxin, will produce a local skin reaction at least 10 mm in diameter. The diagnostic test toxin used in this work contained 5,000 skin test doses per cubic centimeter. All individuals were injected intracutaneously with 0.1 cc of this test toxin. Those showing a skin reaction of 10 mm or over in diameter were considered susceptible and were later injected with the immunizing toxin. Since it was believed that skin tests with one toxin should be sufficient to demonstrate the point in question, the children were not subjected to tests with toxins of all four types. The immunizing toxin, on the other hand, was composed of an equal mixture of toxins of the four types and contained, in all, 5,000 skin test doses per cubic centimeter, approximately 1,250 skin test doses in each of the four toxins. The susceptible children to be immunized were divided into two groups. One group was given three injections of the following doses of the mixed toxin one week apart: 0.1 cc, 0.5 cc, and 1 cc equivalent to 8,000 skin test doses in all. The other group was given four injections, also one week apart, the doses

VERRUGA PERUANA (CARRION'S
DISEASE)

BASED ON PERSONAL EXPERIENCE IN PERU

HOWARD FOX, MD
NEW YORK

My principal object in a recent visit to Peru was to obtain first hand information of the cutaneous lesions of the disease known in that country as verruga peruana. To understand fully its eruptive phase it is necessary to give a general description of this fascinating and unique disease.

Before the causative organism was successfully cultivated, there was some doubt about the relationship of what was called Oroya fever and the cutaneous eruption known as verruga. As it has now been proved beyond any possibility of doubt that these two supposedly different disorders are in reality the same disease, it is perhaps best to characterize the entire process as Carrion's disease, in honor of the young student who lost his life after a voluntary inoculation.

HISTORY OF THE DISEASE

Carrion's disease probably existed in remote times and is generally thought to have been known to the

Spanish conquerors of Peru. According to Maldonado,¹ however, the condition described by the conquerors as *herruga* was in reality not verruga but yaws and its first authentic mention should date from 1630.

Previous to 1870 little was known of the disease. At that time the transandean railway to the town of Oroya was begun and this was followed by a disastrous epidemic. It has been estimated that there were at least 7,000 deaths among those engaged in this railroad construction, most of the laborers being Chileans. The term Oroya fever by which the disease was known is not appropriate, as it has never been seen in Oroya.

Opinions differed regarding this terrifying disease. Some thought it an entirely new disease, others a modified

Fig. 1 (case 1).—Profuse miliary eruption of three months' duration preceded by fever and joint pains, in a man, aged 21. Lesions show a slight tendency to coalesce. Many are covered with blood crusts. The lesions are mostly yellowish red, some being bright red.

form of malaria or other disorder. Some concluded that Oroya fever was a severe form of verruga.

The view that Oroya fever and verruga were the same disease gained ground until 1885, when the question was apparently settled in its favor by the experiment of Daniel A. Carrion. In his desire to study the symptoms and sequelae of the disease, Carrion insisted on being inoculated from a case of verruga. Unfortunately he contracted the serious type (Oroya fever) and died thirty-nine days after inoculation. Carrion is rightly regarded by his fellow countrymen not only as a most courageous man but also as one of considerable scientific attainments. He proved that verruga was inoculable in human beings and that in all

Fig. 2 (case 1).—Variation in size of lesions and tendency for older ones to be pedunculated.

probability verruga and Oroya fever were different phases of the same disease. As Odriozola² says, the case was similar to "*variola sine variolis*" or "*rubeolae sine rubeolis*."

In arriving at the important conclusion that Oroya fever and verruga were independent conditions Strong and his co-workers³ of the Harvard expedition to South America were doubtless influenced by their failure to find the record of Carrion's experiment. The detailed account of Carrion's illness and autopsy were, however, published by Alcedan⁴ in 1903. The opinions of the members of the Harvard expedition, consisting of four Americans and one Peruvian, all of the highest reputation, carried great weight, though their main conclusion was later proved to be erroneous.

GEOGRAPHIC DISTRIBUTION

Carrion's disease is unique in its geographic distribution, being in all probability confined not only to Peru but to certain restricted areas in that country. It occurs between 8 and 13 degrees south latitude and at an altitude varying from 2,800 to 9,000 feet. The coastal and high mountainous regions are free. The disease appears only on the western slope of the Andes, in certain narrow ravines or canyons with luxuriant vegetation and considerable heat during the day. The small towns and villages where the disease is prevalent are sheltered from strong winds (which would affect insect life), as the ravines are at right angles to the prevailing winds.

SYMPTOMS OF MALIGNANT TYPE (OROYA FEVER)

It is convenient to describe separately the symptomatology of the malignant type (formerly known as

Because of lack of space this article is abbreviated in THE JOURNAL. The complete article appears in the author's reprints.

Read before the Section on Dermatology and Syphilology at the Eighty-Fifth Annual Session of the American Medical Association, Cleveland, June 14, 1934.

Oroya fever) and the benign eruptive type (verrua), although there are innumerable gradations between them

The incubation period is not definitely known, Odriozola estimating it to vary between fifteen and forty days. In the experimental infection of Carrion it was twenty-one days. After a prodromal period of malaise, headache and muscle pains there is a sharp rise of temperature accompanied by chills. Fever is most often of the remittent type. It may disappear for several days and be followed by subnormal temperature, profound weakness and death. When it lessens proportionately with amelioration of all symptoms, the outlook for recovery is almost certain.

Fig. 4 (case 2)—Miliary eruption with scaling and a few blood crusts

A striking feature is the rapidity with which profound anemia appears. There is probably no condition except hemorrhage that can cause severe anemia so quickly. The red cells may decrease to one million per cubic millimeter within three or four days, though this usually takes place in from one to two weeks.

The blood change is a combination of pernicious anemia and leukemia. The anemia is due, as Monge⁵ states, to a disturbance in the regenerative capacity of the blood rather than to its destruction, as there is neither hemorrhage nor any sign of hemolysis in proportion to the diminution of the red cells. Both normoblasts and megaloblasts are numerous in the peripheral blood and have a prognostic as well as a diagnostic importance, the prognosis being better with a decrease of the megaloblasts compared with the normoblasts. The blood also shows in severe cases all the bizarre forms of pernicious anemia. The leukocytes are increased at first and may reach 20,000 per cubic millimeter. The eosinophils disappear and there may be myelocytes and myeloblasts in the peripheral blood. The red cells in addition show large numbers of Bartonella bacilliformis, the causative organism.

Fever and anemia are accompanied by severe anorexia, unquenchable thirst, muscle and joint pains, vomiting, hiccups, attacks of syncope and delirium. Epistaxis and petechiae are common, the latter being the earliest stage of verruga papules. Estimates of mortality vary from 30 to 98 per cent.

SYMPTOMS OF BENIGN TYPE (VERRUGA)

The symptoms of benign (eruptive) type also vary greatly. In infants and young children they are mild or often trifling, as I had occasion to observe on my trips to the Rimac valley.⁶

The period of incubation is not known precisely. According to Arce it is usually between twelve and forty days. In experimental inoculations in animals it varies from eight to sixty days. Two periods of

evolution of the disease are described: (1) invasion (pre-eruptive) and (2) eruptive.

The period of invasion begins with malaise, gastrointestinal disturbances and fever, with more or less intense pain in the muscles and joints, especially of the extremities. Fever, according to Odriozola, is always present and is usually of intermittent or tertian type, stopping a few days before the cutaneous outbreak. Pain and edema are in direct proportion to the severity of the eruption. The blood shows simple anemia and may contain the causative organism in considerable numbers. The average duration of this period is stated by Odriozola to be from three to four months.

Before discussing the eruption of verruga it should be said that the Spanish word verruga is the equivalent of the Latin word verruca, meaning wart. Verruga is an unsatisfactory term, as the lesions seldom have any clinical and never any histologic resemblance to ordinary warts. The word verruga, in common use by the public, corresponds, I should say, to the English word pimple.

The cutaneous lesions are of two main types: (1) miliary, which are situated in the cutis, and (2) nodular, which arise in the subcutaneous tissue. A sub-variety of the nodular type is spoken of as "mula" or mular, to anglicize the word, derived from the fact that mules suffer from the same disease.

Miliary Type of Eruption.—The term miliary is not very suitable, as the lesions vary in size from a small pinhead to a good sized split pea. The eruption, for instance, hasn't the remotest resemblance to the miliary papular syphilid. In general it is symmetrical, particularly when it is profuse.

The favorite sites are the extensor surfaces of the extremities and next in frequency the face and neck. The trunk is usually spared unless the eruption is very profuse. The palms and soles are usually free, and the genitalia are infrequently attacked, though I photo-

Fig. 6 (case 3)—A large nodule appeared over the first metacarpal bone of three months' duration, not preceded by any constitutional symptoms in a girl, aged 10 months. The nodule was hemispherical, hard and painless and covered by normal skin freely movable over it. There were also a few miliary lesions on the face and two on the forearm as shown in the illustration.

graphed one patient with numerous papules on the penis and scrotum. There is a great variation in the number of lesions. Some infants and young children whom I saw in the Rimac valley had only a half dozen papules, while two cases studied in the Dos de Mayo Hospital in Lima (through the courtesy of Drs. Gonzales Oleacea and Voto Bernales) presented profuse eruptions (figs. 1 to 5).

As a rule, the lesions are discrete and often closely aggregated, but at times they show a slight tendency to coalesce. They are said to arise on tiny petechial spots and to increase gradually in size. It is also stated

⁵ Monge, C. M. Verruga peruana o enfermedad de Carrion. *Beibette u Arch. f. Schiffs u. Tropen Hyg.* 29: 244, 1925.
⁶ Through the kindness of Dr. E. A. MacCormack, who aided me in every possible manner, I was able to motor up the Rimac valley and visit the towns of Matecana, Surco and St. Bartolome.

that they occasionally begin as minute vesicles or even pustules. Some of them do not attain full pea sized development, and in all cases a striking feature is the difference in the size of the lesions. This is due to their appearing in crops at varying intervals. At the outset they are all sessile, hemispherical or rounded elevations, some of them eventually becoming more or less pedunculated.

Fig 7 (case 2)—Section of early military lesion in upper corium almost entirely encircled by acanthotic rete under low power. Shows proliferation of capillaries many of which are dilated.

The color is also extremely variable, many of the lesions having a faint pinkish hue while others stand out in bold relief from the pronounced reddish color of varying shade. Some are bright red like little senile angiomas. Their vascularity is evident from the number of blood crusts that are noted, bleeding readily taking place from slight trauma or scratching. From some descriptions and a colored illustration in Odriozola's monograph one would get the impression that all the lesions were bright red. This was certainly not so in my limited experience. The skin between the individual lesions is normal in appearance.

The consistency of the military verrugas is hard at the outset and in many small lesions could I think, be properly described as shotty. As the lesions increase in size and age they become distinctly softer. The overlying skin is smooth and tense in the small lesions, but later in the stage of retrogression it may appear wrinkled or covered with blackish blood crusts.

Subjective symptoms are not a feature of the disease. At the outset a pricking sensation may accompany the appearance of petechiae and in the stage of retrogression an annoying amount of itching may be present.

The duration of the eruption is variable. Odriozola estimates it to be from four to six months on the average, though he states that he has seen a case in which the eruption lasted more than two years. The lesions eventually disappear with or without desquamation and leave no scarring or pigmentation.

Nodular Type of the Eruption—The nodular type is less frequent and the lesions are much less profuse than those of the military type. They originate in the subcutaneous tissue as little hard rounded bodies, which at first cause no elevation of the skin. They can be palpated before they are visible. It is said that they are somewhat tender, though this was not apparent in cases that I observed. The lesions may disappear without enlarging or may increase in size and cause

a varying degree of elevation covered by skin that is normal or somewhat reddish. The favorite sites are the extensor surfaces of the extremities. An example of a well developed large nodule is shown in figure 6.

The so-called mule lesion is merely a large nodule that has broken through the overlying skin and in which secondary infection often takes place. Such lesions are either sessile or pedunculated, are firm and elastic, bleed easily and vary in size from a small nut to a small apple. They occur especially on the knees, though also on other regions including the face and may be accompanied by severe hemorrhage, which endangers the patient's life. These lesions are uncommon and I had no opportunity to see them.

In addition to the skin, the mucous membranes of the conjunctiva, nose, mouth, pharynx and gastrointestinal tract may be the sites of verruga nodules.

The prognosis of the eruptive type of Carrion's disease is nearly always favorable, especially when a generalized eruption appears rapidly and disappears slowly, accompanied by an improvement in the general condition.

Differential Diagnosis of Cutaneous Lesions—The diagnosis is usually easy when one has seen a number of undoubted cases. The eruption as a whole is unique and unlike any disorder of the skin with which I am familiar. Some individual lesions look precisely like granuloma pyogenicum, but I think the eruption as a whole is rather suggestive of multiple sarcomatosis,

Fig 8 (case 2)—Appearance under high power showing increase in number of capillaries of small caliber, marked proliferation of cells of the reticulo-endothelial system and hemorrhage (erythrocytes in the lumens and dispersed among the cells of the infiltration).

especially in the earlier stages before any of the papules have become pedunculated. Jadassohn saw a Swiss guide in Bern who had contracted the disease while climbing in the Andes and stated that the eruption suggested multiple angioma, hemorrhagic sarcoma or telangiectatic (pyogenic) granuloma. Needless to say,

mistakes in diagnosis are made by the public in the verrugous districts and even by physicians. A patient whom I saw at Surco stated that he was suffering from verruga. If I had seen this man in the United States I would have considered his eruption to be a typical molluscum contagiosum. I still feel doubtful about this case.

EPIDEMIOLOGY

Carrion's disease occurs in both sexes, in all races and at all ages. It may appear in the new-born, when it is usually of severe type. Odriozola quotes a single case of apparent intra-uterine infection. The disease is, however, not hereditary in the strict sense of the word. It is inoculable but not contagious.

In the verrugous zones practically all natives are infected in infancy or early childhood and are thereafter immune. Gomez⁷ from an extensive epidemiologic study, concludes that in the first years of life (up to ten or more years) the disease is almost always of the benign type, tending to acquire extreme severity in adolescence and adult life. In the Rimac valley I saw five infants from 8 to 9 months of age all of whom presented sparse but typical eruptions and appeared in perfect health. In no case was there a history of any but the mildest constitutional disturbance before the appearance of the eruption. A day or two of malaise or fever had been noted by some of the mothers. Most of the well marked cases of the disease are seen in strangers who visit the verrugous regions and remain there during the night. While one attack confers lasting immunity, there are occasional recurrences. Odriozola refers to cases in which this took place three and five years respectively after infection. In a personal communication Dr. Edmundo Escobel states that he has recently seen a malar type of lesion on the great toe of an individual who had been infected with verruga eighteen years previously. The verrugous nature of the lesion was proved histologically. While the disease may be acquired at any time of year the majority of infections occur between the months of December and March.

BACTERIOLOGY

Alberto Barton⁸ in 1909 expressed the view that bacillus-like bodies which he had previously described in the erythrocytes of cases of the malignant type of Carrion's disease were the probable cause of the disease. These bodies were later named *Bartonella bacilliformis* by Strong and his co-workers, and they have been definitely proved to be the causative organisms. They are thought to be bacteria by Noguchi⁹ and by Aldana.¹⁰

The organisms are best seen in smears stained by the Giemsa method and appear as rounded or rod shaped bodies, the rodlike forms measuring from 1 to 2 microns in length and from 0.2 to 0.5 micron in width. They appear singly, in pairs and in end to end chains and frequently assume a V or Y form. The round bodies measure from 0.3 to 1 micron in diameter and occur isolated or in groups. A red cell may contain one or many organisms.

According to Aldana, *Bartonella bacilliformis* is not an endoglobular parasite, as has formerly been considered. In his opinion it is merely adherent to the

red cell, its situation on the cell being accidental and due to breaking up of endothelial cells of the blood capillaries. Bartonella, he says, does not destroy the red cell, nor does it require these cells for its multiplication.

Bartonella bacilliformis is seen not only in the peripheral blood but in most of the tissues and organs of the body. It has doubtless been observed in the cutaneous lesions a fact of great importance as another proof that so-called Oroya fever and verruga are the same disease. At least it can be said that bodies indistinguishable from *Bartonella* have been found in the verruga lesions. These were first described in 1913 by Mayer, da Rocha Lima and Werner¹¹ as inclusion bodies closely resembling parasites of the chlamydozoa group. Their presence was later confirmed by Mackehenie and Battistini,¹² and in experimentally produced lesions by Mackehenie and Weiss¹³ and by Marques da Cunha and Muniz.¹⁴

Cultures—In his most recent and excellent article on Carrion's disease, da Rocha Lima¹⁵ states that *Bartonella bacilliformis* was first cultivated by Noguchi and Battistini in 1926. This is not entirely correct as the records show that Battistini¹⁰ reported successful cultures in 1925. It is also stated that Herccelles cultivated the organism in the same year.

Bartonella bacilliformis is a gram-negative, obligate aerobe, which is usually nonmotile. It grows in solid or liquid mediums containing whole blood, plasma or serum (Aldana) and only below 37°C. The organism may be isolated by blood cultures from patients in both anemic and eruptive stages and even at times after the disappearance of the eruption.

HUMAN INOCULATIONS

Mention has already been made of the experiment practiced on himself by the young student Carrion. The inoculation was made under protest by his friends, who realized his danger. Thinking that this memorable experiment settled the question of unity of the two types of the disease and realizing the danger of human inoculations, Peruvian physicians have refrained from carrying out further experiments on man.

Strong and his co-workers inoculated a volunteer Chilean with material taken from two cases of verruga. On the sixteenth day cherry red papules appeared at the site of the inoculation and were histologically "similar to other early human lesions of the disease." There was no appreciable anemia and the blood showed no *Bartonella*. From this experiment they concluded that "direct inoculation of the verruga virus from man to man does not produce Oroya fever." As a matter of fact, it merely showed that inoculation of verruga material could produce verruga.

An accidental inoculation of a Peruvian physician furnished another proof of the identity of so-called Oroya fever and verruga peruana. The procedure in this case was the reverse of Carrion's experiment. This physician (O. G. R.) gave me the following description:

of his infection. He was accidentally inoculated in February 1931 by a needle prick while giving a blood transfusion to a patient with the malignant type of Carrion's disease. Fever appeared eight days later without premonitory symptoms and rose to 40.4 C (105 F). During the following three weeks it continued with slight remissions between 38 and 39 C (100.4 and 102.2 F). The blood showed four million red cells and 4,800 leukocytes. Ten days after the disappearance of the fever he suffered from intense pains in the extremities. Several days later there was an eruption both of miliary and of nodular type, which disappeared at the end of ten months and did not recur.

ANIMAL INOCULATIONS

It is the consensus in Peru that many animals suffer spontaneously from the eruptive type of verruga, though little study of this question has been made. The fact that various animals can be artificially infected is, as has been said, no proof that they acquire the disease naturally.

The first undoubted transference of the disease to animals was made by Jadassohn and Seiffert,¹⁷ who in 1910 inoculated monkeys and carried the infection through three generations. Subsequent successful inoculations in monkeys were made by Mayer, by da Rocha Lima and Werner, by Arce, Mackehene and Ribeyro,¹⁸ by Strong and his co-workers, by Noguchi, and by others. Other animals that have been successfully inoculated include the dog, sheep, goat, ass and rabbit (intratesticularly).

Further proof that Oroya fever and verruga are the same disease is shown by the following animal experiments. In two monkeys inoculated locally from verrugous lesions by Mayer and Kikuth,¹⁹ there were severe fever and anemia with changes precisely like those in man, with swarms of Bartonella in the blood and a fatal termination. Noguchi²⁰ also showed that Rhesus monkeys that have recovered from infection with the Oroya strain of Bartonella are completely immune to the verruga strain.

Experimental animal infections have usually been obtained by direct inoculation of verrugous material in the skin, less often by cultures and almost never with blood, even when it swarms with Bartonella. Mayer and Kikuth observe in this regard that "further cultural experiments and inoculations should show whether all the developmental stages of the virus are communicable and whether various diseases or conditions are necessary (condition of the reticulo-endothelial system and injury from other infections)."

TRANSMISSION BY PHLEBOTOMUS

The first suggestion that Carrion's disease might be transmitted by some blood sucking insect was made by Arce in 1889. The first extensive investigations were made by Townsend,²¹ who worked for two years (1912-1914) in the Rimac valley. He demonstrated conclusively that the disease is transmitted by a species of phlebotomus, which he named *P. verrucarum*. He was

able to exclude mosquitoes, flies, fleas, lice, bedbugs, ticks and mites as possible vectors.

Shannon²² later corroborated Townsend's views regarding transmission and added another new species of phlebotomus as a vector, which he named *P. Noguchii*.

The following ecologic evidence that phlebotomus is the vector of verruga was stated by Shannon. As the disease is contracted only in certain zones, during the night (with possible exceptions) both indoors and far from habitation, at any time of the year, he concluded that the vectors must be common blood suckers of man restricted to verruga zones, nocturnal in habits and able to breed in unrestricted situations. In order that the adults (which have a very restricted flight) may be practically omnipresent, they must continue active throughout the year.

According to Shannon, *P. verrucarum* and *P. Noguchii* conformed to all these requirements, while all other blood sucking arthropods could be excluded. *P. verrucarum*, he stated, appeared to be predominantly a domestic species, while *P. Noguchii* occurred consistently outdoors. This probably explains, Shannon stated, why the disease may be contracted indoors and outdoors, at times miles from any habitation.

POSSIBLE RESERVOIR OF VIRUS

As certain native and domestic animals in the infected zones are susceptible to the disease, Townsend thought there was apparently no need of a natural reservoir and possibly, he said, none exists. He then made the following significant statement: "It seems curious that man becomes so quickly infected when there is such a comparatively sparse animal and human population existing in most parts of the region." He added "Possibly there are other sources from which they obtain the infectious material." The possible sources may be certain lactescent plants, as indicated in the following paragraphs.

After a careful study of the plant life in certain verruga canyons, Maldonado²³ in 1930 found that certain plants were characteristic of these zones and that they did not exist in nonverrugous areas. This suggested that they might play some causative role, first as a reservoir of the virus and secondly as food for the insect vector. The plants in question were the lactescent ones commonly known as huanarpo macho (*Euphorbiaceae* family) and the huancayo (*Julianaceae* family). He subsequently²⁴ (1932) affirmed that the conditions necessary for the lactescent vegetation and the phlebotomus are the same in whatever part of Peru they may be studied.

Mackehene and Coronado²⁵ in January 1933 found in the juice of specimens of huanarpo macho bodies very similar to Bartonella, when using appropriate stains. Under aseptic precautions, cultures were obtained from the latex of the plant showing the characteristics of Bartonella. Cultures from another species of euphorbia, when injected into the anterior chamber of a white rabbit, caused an iridocyclitis, from which the organisms were cultivated and found pathogenic.

for guinea-pigs. The authors also observed small insects on the trunks of these plants belonging possibly to the family of psocidae. Organisms found in the digestive tract of these insects were easily cultivated and were virulent to a guinea-pig that suffered from nervous symptoms, including paralysis. Agglutination was obtained by the plant virus and that from the insects in contact with serum from a convalescent verruga patient in two cases at a dilution of 1 to 1,600. The authors concluded that the organisms obtained from the latex of the plants and from the insects could be placed in the genus *Bartonella* based on their morphology and experimental reactions. Monkeys were unfortunately not available at the time for experimentation.

PATHOLOGY

According to Hercelles,²⁶ hemorrhage and thrombosis are the principal changes that are constantly present in the malignant type. Most of the tissues and organs may be affected. *Bartonella* has been cultivated from many of them, notably the kidneys, lymphatic glands, spleen and bone medulla.

Weiss²⁷ speaks of the two types of the disease as hematic and histoid. The former is characterized by the presence of *Bartonella* in the circulating blood. In the histoid type the organisms limit their activity to the reticulo-endothelial system and cause degenerative-exudative reactions. He considers the formation of verrugous (eruptive) lesions to be an allergic reaction to the virus. It is interesting to note that in the histoid stage Weiss was able to show verrugous changes in the skin microscopically before they were macroscopically visible.

Histopathology of Verruga Lesions—Opinions about the histologic structure of verruga lesions have varied. Some of the earlier investigators considering them to be a fibrosarcoma or suggestive of either sarcoma or angioma. Hercelles²⁸ thought that they were of vascular origin due to periarteritic proliferation. Escomel²⁹ considered the process to be inflammatory rather than neoplastic and thought what he termed "verruca cells" to be the characteristic element and that they arose from connective tissue cells.

Cole³⁰ thought that the lesions were granulomas with special histologic changes, characterized by dilatation of lymph vessels and choking of their lumens with mononuclear and polymorphonuclear leukocytes. There was also perivascular infiltration of plasma cells, fibroblasts, mononuclear and relatively few polymorphonuclear leukocytes and the formation and dilatation of many blood capillaries with marked edema and extravasation of red cells in the tissue.

Strong and his co-workers summarize the changes as follows: "The verruga nodule constitutes a special form of granuloma characterized in the early stages by the formation of new blood vessels in edematous connective tissue and by marked proliferation of the angioblastic cells forming masses or islands of closely placed cells, by the invasion of the connective tissue by lymphocytes, plasma cells and leukocytes and as the lesion progresses by the formation of fibroblasts and the deposit of collagen fibrils." They stated that the

verruca tissues may have at times a sarcomatous, at times a myxomatous or at times an angiomatous (cavernous) appearance.

Rocha Lima, who has written extensively on this subject, summarizes the histogenesis of the verruga lesion in saying that the "basic process in the formation of verruga tumors is a growth of vascular elements."

HISTOLOGIC EXAMINATIONS

Three biopsies were obtained from two patients, the histologic examinations being made by Dr. T. J. Riordan.^{31a}

TREATMENT

Treatment is purely symptomatic, no specific drug or vaccine having been found to be of real value, though Arce³¹ (quoted by Noguchi) recommended small doses of arsphenamine. Blood transfusions have proved to be very disappointing and in the opinion of some Peruvian physicians are contraindicated. Blood from a nonimmune donor, according to Weiss, acts like a culture medium for the organisms. It would be interesting, he says, to try the effect of blood from an individual in the histoid (eruptive) stage.

Prophylaxis is all important and consists chiefly in remaining away from verruga zones from sundown to sunrise. According to Townsend, no one has ever been known to acquire the disease unless he has spent one or more nights in infected districts.

SUMMARY

The diseases formerly known as Oroya fever and verruga peruana have been definitely proved to be phases of a single process, conveniently called Carrion's disease. They are restricted to certain parts of Peru and present several unique features. The malignant type (Oroya fever) shows a profound anemia occurring more rapidly than in any condition except hemorrhage, and the eruptive stage (benign type) differs from all known skin diseases. The causative organism (*Bartonella bacilliformis*, Strong) has been demonstrated morphologically and by culture in the circulating blood, inner organs and eruptive (verrugous) lesions. Infection with one type is followed by immunity to the other, both in human and in experimental animal infections. Human and animal inoculations of one type may produce the other type of the disease. The insect vector (certain species of *phlebotomus*) has been discovered and possibly the existence of a plant reservoir. There is no specific treatment.

In addition to help from physicians mentioned in the text, I received advice and assistance from Drs. Monge, Barton, Escomel, Hercelles, Mackehemie and Weiss.

140 East Fifth-Fourth Street

ABSTRACT OF DISCUSSION

DR. HAROLD N. COLE, Cleveland. There will probably not be many cases of verruca peruana encountered in the United States, but once in a while one of them wanders into Panama or somewhere in the Southern states. There is no question about the condition being a very characteristic granuloma in its clinical and also its histologic appearance. One who has studied a case will never forget the formation of new vessels, the hemorrhage into the tissues, the eosinophilic fibroblast and plasma cell infiltrations in the local tissues. I think it is well that Dr. Fox has brought out the change in conception since

the report of the Harvard commission After the Harvard commission came back, Dr Strong kindly sent me a copy of its monograph, and apparently it had drawn some wrong conclusions and felt that the diseases were separate, while it seems that they actually are the same condition I was interested in Dr Fox's remarks in regard to the mild type of the disease in little children I was wondering whether possibly these children, owing to the influence of the mother's blood, because all the inhabitants in that neighborhood have had the disease, might show a certain resistance to the disease and therefore contract it simply in a mild form It is a most interesting problem for the immunologist, and I predict that one of these times another commission is going to be sent down there and it will work out some method of taking care of the population and ridding it entirely of this disease

Dr. HOWARD FOX, New York In the time at my disposal I could only touch on the more important points The eruption of verruga peruana is unlike anything I have ever seen Some of the lesions look like angioma and some like granuloma pyogenicum, but taken as a whole it suggests a generalized sarcomatosis in many ways Dr Cole's question as to why children have such a mild attack is one that I cannot answer I had previously asked the same question of some Peruvian physicians, who could give no answer to it

EPIDEMIOLOGIC FACTORS IN MEASLES PROPHYLAXIS

SAMUEL KARELITZ, M.D.

AND

BELA SCHICK, M.D.

NEW YORK

In using immune adult blood serum in the prophylaxis of measles, we observed that the interpretation of our results depended largely on whether certain epidemiologic factors were taken into account Under relatively constant conditions the results obtained in institutional exposures seemed good, the percentage of complete protections was high, whereas under similar conditions, with the exception that the children were exposed to their sick siblings at home after prophylactic treatment, the percentage of protections was very much smaller We have therefore divided 263 cases treated with immune adult serum according to the circumstances of their exposure to measles in an attempt to answer the following questions

1 How do the results obtained with serum injected prophylactically into children exposed to measles in institutions compare with those obtained under similar conditions in private homes, that is, in children exposed to their sick siblings and treated at home?

2 Can this difference be obviated or reduced by increasing the size of the dose or the potency of the serum?

3 Are the results in all homes the same, or do they vary with the hygiene?

INJECTION OF SERUM IN HOSPITAL AND IN HOME

The cases treated with the serum obtained from five blood donors are charted (chart 1) according to whether they were exposed to measles while in institutions or to sick siblings at home It is evident that, with the same dosage of serum injected in children of comparable ages and exposed to measles for similar periods, the percentage of presumably protected cases was

greater in hospitals than in homes This was true for each of the five donors Compositely of 134 cases there were 87 per cent protections in hospitals against 29 per cent in homes, the modifications were 13 per cent in hospitals and 22 per cent in homes, and the failures were 0 per cent in hospitals and 49 per cent in homes (chart 2, columns 1 and 2)

A few specific experiences may serve well in illustrating the point just made In an outbreak of measles among the 3 year old children at the S V Hospital, eighteen children were each injected with 6 cc of serum obtained from donors Q and R All remained free of measles

In one control case the disease developed At the B J Hospital ten out of twelve children, each injected with 6 cc of K serum, remained well, in one child typical measles developed and in one the modified type of the disease

Although the results seem excellent and although in previous outbreaks of measles at the B J Hospital there were usually 100 per cent cross infections, comparison of these results with those obtained with the same serum injected in patients exposed at home (chart 2, columns 1 and 2) shows a striking difference the percentage of protections being very much less in the latter group

We may infer corroboration of our results from the report of Park and Freeman,¹ which reveals that of 652 patients exposed from one to six days in institutions and injected (chart 2) with 6 cc of convalescent serum, 91 per cent were protected 7 per cent of the

Chart 1—Results of use of serum of individual donors in homes as compared to hospitals conditions otherwise similar In these charts the solid black column indicates protected cases vertical lines indicate modified cases and the crossed column indicates un protected cases, H hospital cases and F familial or home cases

cases were modified and only 2 per cent were unaided, whereas of 226 patients treated at home under otherwise similar conditions, only 52 per cent were protected, but 42 per cent of the cases were modified The data of Levinson and his co-workers² for convalescent serum used in homes are very similar to those of Park and Freeman

SIZE OF DOSE OR POTENCY OF SERUM

It seemed reasonable to expect that by increasing the dosage of the serum employed an amount would be reached at which practically no difference would be observed in the percentage of protected cases in hospitals and in homes. Chart 2, columns 2, 3 and 4, demonstrates that this prediction was warranted. The first two columns indicate that in 134 cases, quite similar to the group referred to in chart 1, the results were very much alike, 83 per cent of the cases treated with 6 cc of serum in hospitals were completely protected and 17 per cent were modified. In homes with similar dosage the completely protected were 29 per cent, the modified 22 per cent and the failures 49 per cent of the cases. When the dosage of serum was increased to 8 cc (column 3) and was tested only in homes, there was a rise of protected cases from 29 per cent to 46 per cent and in modified cases from 22 per cent to 43 per cent. The failures dropped from 49

Number of cases

Chart 2—Diminution in the discrepancy between the percentage of complete protections in homes as compared to hospitals with increasing dosage of serum. In this chart H indicates hospital exposed cases, F cases exposed at home.

per cent to 11 per cent. When dosages of from 12 to 25 cc of adult serum were used for a group of children treated at home (column 4) of somewhat greater age range, from 2 to 12 years, but otherwise under similar conditions, there was a rise in the complete protections that were obtained from 46 per cent (with 8 cc dosage) to 57 per cent.

Corroboration of these statistics may be deduced from the results reported by Morales and Mandry³ (chart 2, columns 5, 6 and 7). They show a striking agreement with our results. With 10 cc of adult serum they obtained 41 per cent against our 46 per cent with 8 cc. With 15 to 30 cc they had 58 per cent protections against our 57 per cent with almost similar serum dosages. Morales and Mandry show 82 per cent protection with 30 cc of adult serum and 85 per cent with 40 cc of serum. When from 4 to 6 cc of convalescent serum was used, they had 84 per cent protection.

Few reports have shown similar results in hospitals and homes, but only when convalescent serum has been

employed in adequate dosage. Nabarro and Signy⁴ (chart 2, columns 11 and 12) reported 97 per cent protected in hospitals and 94 per cent in homes when from 5 to 7 cc of serum was used.

INFLUENCE OF HYGIENE

The fact that disease seems to spread more rapidly in congested districts and, above all, in those in which the

hygiene is very poor suggested further analysis of our statistics with the hope of answering question 3, must we qualify our results according to the type of home in which the exposure takes place? If one considers a home of good hygiene in which the sick child is quickly isolated after the illness is discovered, and compares it to one in which the hygiene is poor (one in

3 Morales E G and Mandry O C. Relative Prophylactic Value of Convalescent and Immune Adult Measles Serum, Am J Dis Child 38: 1214 (June) 1930

4 Nabarro, D N and Signy A G. Convalescent Serum in the Prophylaxis of Measles, Brit M J 1 12 (Jan 3) 1931 2 599 (Oct 3) 1931

which the sick and well children continue to be together after discovery of the illness) a striking difference in the results is demonstrable. Thus, if 106 children of from 2 to 6 years of age, exposed for from two to five days and injected with 6 cc of serum are divided into those exposed in homes of good hygiene in those of bad hygiene and in the hospital, the percentages of completely protected cases are respectively 58, 0 and 83 (chart 3).

The difference in the results in homes of good and of bad hygiene is almost as striking as the results of patients treated with adult serum when tested in hospitals is compared to homes. In the home of poor hygiene the exposed child obtains the infection not only from one to five days before the serum is injected but throughout the period of infectivity of the sick sibling. Such a child may receive so great an infection that complete protection can be obtained only if a large dose of serum is given. This was apparently borne out by the fact that with increasing dosage of serum there was a progressively greater percentage of protected cases.

COMMENT

This influence of epidemiology in measles prophylaxis has been emphasized before. Jordon,⁵ realizing that contact is much more intimate in home life than in hospitals, recommended larger doses of convalescent serum (from 6 to 18 cc).

Park and Freeman, using 6 cc of convalescent serum in institutions and at home, found striking differences in the percentage of children who were completely protected. The relation of hospital to home protection was 91/52.

Freeman and Freeman⁶ stated that "in judging the results of a series of institutional children, the definiteness of exposure can never be accurately determined and it is safe to say that a good many of the children recorded as completely protected were never exposed."

The data of our 263 cases, when studied from the point of view of epidemiology showed strikingly how different the results were with serum tested in the wards of hospitals or institutions as compared to familial exposures. The excellent results obtained in hospital wards were just as striking as were the poor results obtained in homes, under otherwise comparable conditions. Our results probably explain the high percentage of completely protected cases usually obtained with relatively small doses of serum when injected into susceptible children exposed to measles in schoolrooms, play groups, nurseries, asylums and especially children's hospitals.

Although it is true that, in such institutional epidemics of measles, all exposed susceptible children may develop the disease after the first exposure, it is far more common for only a few to come down with it after the first exposure and others after the second or

third exposure. Under such circumstances it is doubtful whether a prophylactic procedure can be evaluated very accurately. It is safe to presume that in hospitals many of the so-called exposed children escaped infection entirely, while some may have been slightly infected and others infected intensively and repeatedly throughout the period of exposure. In pediatric institutions where there is a cubicle system or where isolation technic is observed, this difference in exposure must be evident.

A brief description of an experiment, a preliminary report of which has been published,⁷ will serve to illustrate the importance of the epidemiologic factors pointed out in this paper. We undertook a study attempting to increase immune antistances of adults by reexposing them frequently and intimately to patients in the first few days of severe measles. Four volunteers were bled before, and eight and twenty-one days after the last of thirteen exposures to the disease of from thirty to sixty minutes. One hundred and eighty-two susceptible children exposed to measles for from two to five days were treated with serums of the four volunteers. Serum B refers to that obtained before reinfection, and A₈ and A₂₁ to serums obtained eight and twenty-one days after the last exposure. The latter were so similar in their results that they will be generally considered together as A. The results with the serum of donors M, K, S and R are reported compositely and represented in columns 1 and 2 of chart 4. One hundred and seven children from 2 to 6 years of age who were exposed for from two to five days received 6 cc of serum obtained from one of the four donors. Of the thirty-six

injected with B serum, 39 per cent were completely protected, 15 per cent had modified measles and 46 per cent had unaltered measles. Of the seventy-one who received serum A, 63 per cent were protected, 26 per cent had modified measles and only 11 per cent developed ordinary measles.

If these statistics are accepted at face value they indicate a marked increase of measles immunity following repeated reexposure to the disease. If, however, the epidemiologic factors discussed are applied to this study, the striking improvement that seemed to have been noted becomes much less evident, almost doubtful. Thus, if the 107 cases previously referred to are separated into hospital exposures and family exposures, we note that in the hospital group there were no failures in forty-eight cases, whereas the unprotected cases of the home (familial) exposures were numerous, twenty-five out

Chart 3—Results in 106 cases of injection of serum under standard conditions except for exposure. FH6 indicates homes of good hygiene. FH6 homes of bad hygiene and H6 hospital.

of fifty-nine, or 42 per cent. The difference between the percentage protected with serum A over that with serum B is thus greatly reduced. If, therefore, the conditions of the experiment were alike in all details except that the exposure to measles occurred at home rather than in the hospitals, we noted a striking difference in our results. The same observation was true for each donor studied, as demonstrated in chart 1. Furthermore, when the dosage of serum was increased from 6 to 8 cc (chart 4, columns 7 and 8) and was tested in homes only, the number of completely protected cases increased but there was almost no difference in the results obtained with serums A and B. The latter experiment again demonstrates the necessity of considering the epidemiologic factors in studies of measles prophylaxis.

We believe that the evidence presented indicates clearly that the degree and frequency of repetition of exposure to measles within a few days determines in large measure whether the susceptible patients will develop the disease. In this respect it is not unlike tuberculosis and perhaps other infectious diseases.

The inadequacy of most hospitals and institutions for study of the prophylactic value of an antimeasles serum has been demonstrated. We would suggest that a serum may be declared effective only if it has been proved to be so after it has been tested under the severest conditions, namely, thorough and repeated exposure to sick siblings at home, or under comparable epidemiologic circumstances.

CONCLUSIONS

1 Hospital and institutional wards are usually inadequate for study of measles prophylaxis because of the uncertainty and difference of the intensity and duration of the exposure of the susceptible children.

2 The percentage of completely protected cases in homes varies with the hygiene, the greater number of protections being recorded in homes of better hygiene or in those in which facilities make possible isolation of the sick child at an early stage of the disease.

3 The percentage of complete protections in homes of poor hygiene increased progressively with corresponding increase of the serum dosage.

4 We believe that the evidence presented indicates rather clearly that the degree and frequency of infection with measles within a few days determines in large measure whether the disease will develop in the susceptible children. In this respect it is not unlike tuberculosis and other infectious diseases.

Lengthening the Prime of Life—It was coming to be thought that longevity was determined only by heredity, and that "while there are many ways in which you can shorten your life, the only way to lengthen it is by the selection of a longer-lived ancestry." We now know that this was a too fatalistic view and that, important as is the inheritance, the life cycle can also be extended by simple improvement of food habit such as is easily within individual and family control. And it is important to realize that this increased length of adult life induced by taking a larger proportion of the needed calories in the form of the protective foods means a longer prime of life, not merely a longer old age. The prime of life is in fact extended in considerably greater ratio than the life cycle as a whole, and it is extended in both directions, development being expedited and old age deferred in the same individuals by the same improvement in an already adequate food supply—Sherman, H. C. Food and Health, New York, Macmillan Company, 1934.

Clinical Notes, Suggestions and New Instruments

GRAPHIC METHOD OF INTERPRETING BLOOD VESSEL DISEASE OF THE LEGS. PRELIMINARY REPORT

BERTRAM M. BERNHHEIM, M.D., BALTIMORE

From the Surgical Department of the Johns Hopkins Medical School

When one sits with the legs crossed there is an almost invisible but natural swing of the foot that is synchronous with each heartbeat. If one attaches a short rod¹ to the side of the shoe of an individual sitting thus and lets the pointed tip of this rod rest lightly against the revolving drum of a sphygmograph, one will get a normal reading such as those in figures 1 to 5.

These graphs, as will be noted, show a dicrotic wave and correspond very closely to the sphygmogram tracings of the

radial artery. There are slight variations, as one would expect, and many more control readings will have to be taken in order to get a clear idea as to just what they are and what they mean. They are being taken right along and there will be more to say on the matter later. Cardiac conditions and other factors must naturally be of some influence.

In making the tracings the one leg should be crossed over the other in such a way that the upper ends of the heavy calf

¹ So far as the observations go—and of course this is subject to change—the length and character of the recording rod does not seem to be of great importance other than that the very tip should be fairly delicate and flexible. At present a rod is being used made of a light narrow rigid piece of wood 8 inches long to which by adhesive tape an ordinary thin strip of tin is attached on the end of which, again by adhesive tape, there is attached a short piece of pointed x-ray film the whole affair being about 11 1/4 inches long. This contraption is attached to the inner side of the shoe at the sole by adhesive tape in such a manner that it projects about 6 inches beyond the tip of the shoe.

muscles rest on the patella. If the leg is crossed over too far the foot may have, and usually does have, a swing that gives a normal reading, but this swing is not as wide as is the case if the leg rests on the patella and consequently the peaks of the curve are not as high or as definite. Naturally, the individual should be as relaxed as possible and let the foot hang

free. It is also best for him not to look at the drum as the tracing is being made.

In the case of those who are suffering from blood vessel disease of the legs it has been found that the swing is much less than normal, even entirely absent, depending on whether the popliteal artery is partially or totally obliterated, and the status of the collateral circulation. It has further been found that many of these legs when crossed and placed for a reading have more or less of a tremor, very fine in some, rather gross in others, which gives an irregularity to the line of the graph. Certain normal individuals present a similar phenomenon, but it seems to be more commonly found in the diseased.

Before the test was tried on those with diseased blood vessels, it was felt that, if the popliteal artery was pulsating, a normal reading would be obtained but this has proved to be far from true. Many patients whose popliteal artery can be felt—as in the case of Mr G D—even well felt, present a very sad looking graph, so that the conclusion is reached that this test reveals very accurately the state of the leg's circulation, both natural and collateral. The less the swing, the more serious the condition, the greater the swing the more positive and regular, the better the condition.

Curiously enough, though, no matter how good the circulation of a leg presenting vascular disease may be, the graph of

that leg never seems to approach the normal with its dicrotic wave. Certain ones have suggested it but could not be considered truly normal and one wonders whether a leg the normal blood channels of which have become obliterated can ever show such a thing. In every instance thus far in which a dicrotic wave has appeared constantly, palpation has revealed pulsating arteries in the entire leg and foot. Indeed, it would appear that—aneurysms possibly excepted and perhaps, to a certain extent, vasospasm—a plainly visible, regular foot swing indicates a normal circulation. One need not make tests, take graphs or palpate the vessels.

Fig 12—Arteriosclerosis and gangrene of left big toe in G D, a man aged 70. Pain in the left leg. Threatened gangrene of the left foot. Intermittent claudication. Both femoral pulses felt. Both popliteal pulses are felt but the left is only fair. No pulses in either foot. Circulation poor in both legs better in the right than in the left which is the one affected. The patient was a thin man with blood pressure of 200 systolic, 95 diastolic, and the popliteal pulses were better felt than in any of the other cases reported yet the graph shows that the circulation is anything but good thus indicating that pulsation in the popliteal arteries is not necessarily a guide to the true state of the circulation below.

For the time being, opinion must be reserved as to the explanation of the phenomenon, but it has been suggested that it is due not to the pulsating popliteal artery itself but to the synchronous spread of the calf muscles consequent on the amount of blood sent to them.

It is thus apparent that here is a very simple and inexpensive method of graphically determining the state of the arterial circulation of the legs in both health and disease. And not only that, but by this method it will be possible by successive readings over a period of months or years to keep a pictorial record of such increase or decrease of the circulation as may take place.

This is a preliminary report and further work is in process, but it may be permissible to say that there are rather wide implications to this finding and much that is of interest awaits future studies. A further report will be made.

HYPERSENSITIVENESS TO PITUITARY EXTRACT

FRANK A. SIMON, M.D. LOUISVILLE, KY

The continual increase in the administration of various biologic products by the several parenteral routes warrants an occasional word of caution with regard to the development of hypersensitiveness.

It is well known that this artificially produced hypersensitiveness is usually not of the strong, atopic type. Atopic hypersensitiveness may, however, under certain conditions, be produced artificially by injection. These conditions are for the most part unknown at the present time.¹ Hypersensitiveness of varying degrees results from injections of horse serum preparations. Sensitization to insulin is a well recognized condition.² Pituitary extracts, however, judging from reports in the literature, very rarely produce clinical hypersensitiveness. Hasson³ in 1930 and Wang and Maxwell⁴ in 1933 each report a case of general reaction following the injection of pituitary extract.

REPORT OF CASE

H. F., an American housewife, aged 28, in good general health, without personal or family history of allergic diseases, has had seven children. Following the birth of two of her first five children she was given a subcutaneous injection by her private physician (presumably pituitary extract). Her sixth baby was born in November 1933. Following delivery the usual subcutaneous injections of pituitary extract and ergot were given. There were no untoward symptoms following any of these injections. Her seventh child was born Nov. 8, 1934, and again the usual subcutaneous injections of pituitary and ergot were given. About thirty minutes later massive swelling

of the lips and face was noted and the patient complained that her tongue felt tremendously swollen. She began to have difficulty in breathing, which was evidently due to obstruction in the upper respiratory tract. The edema of the larynx increased rapidly and she had more respiratory difficulty. The administration of epinephrine relieved the situation and she recovered completely. The puerperium was uneventful until six days after delivery, at which time a generalized urticarial rash occurred with considerable itching and discomfort. This lasted five days and gradually subsided, leaving the patient feeling very well.

Skin tests on the patient, done by the scratch method, gave the results recorded in table 1.

From the Department of Medicine, University of Louisville School of Medicine.

¹ Coca, A. F., Walzer, Matthew, and Thommen, A. A. Asthma and Hay Fever in Theory and Practice, Springfield, Ill., Charles C. Thomas, 1931, p. 56.

⁴ Wang, P. W., and Maxwell, J. P. Protein Shock After the Administration of Pituitrin. Chinese M. J. 47: 66 (Jan.) 1933.

The preparations listed in table 2 were made by emulsifying the fresh gland or other material in phenolized buffered saline solution (Alice Evans' solution). Tests were made by the scratch method.

Extracts of the following human tissues gave negative tests: pancreas, adrenal, liver, thyroid, spleen, brain (pons) and kidney.

Forty-five common foods, pollens, danders and other inhalants all gave negative tests. All tests, both positive and negative, were done in duplicate. All substances giving positive tests were applied in the same way to a normal person with negative results.

Skin tests done on the baby thirteen days after birth were entirely negative to the same pituitary extracts used in testing the mother.

Local passive transfer (Prausnitz-Kustner) with the patient's serum was strongly positive in each of the two recipients. The

reaction in the prepared areas of these recipients could be elicited very well by the scratch method and also by the intradermal method. The controls were negative.

COMMENT

The development of a specific hypersensitiveness with local passive transfer of antibodies to the injected substance, pituitary extract, in a patient without personal or family history of allergy and with negative tests to the common allergens is worthy of note. This is particularly interesting in view of the fact that pituitary extract is used so extensively and allergic manifestations from it are reported so rarely.

No one particular brand is responsible, since positive skin tests were obtained with four different brands.

Pitressin, containing the vasoconstrictor principle, gave a positive test, but pitocin, containing the oxytocic factor, gave a negative test.

The specificity is not directed toward some species specific factor distributed throughout the various tissues of some particular animal, or even toward the brain tissue of a particular species of animal. It is apparently directed toward some constituent of the posterior lobe of the pituitary gland of several animal species, including man himself. So far as I know this is the first recorded instance of a definitely established hypersensitiveness in man to a product of the human body. The late Bruno Bloch, for several years preceding his death, sought unsuccessfully to find a case of hypersensitiveness to a product of human metabolism.⁵ Considerable theoretical importance attaches to this problem, since, if it could establish that a man could be sensitized to a product of his own body, it might offer a possible explanation for the existence of certain possibly allergic diseases which appear to be of intrinsic origin, such as certain types of asthma, eczema, urticaria and migraine.

In the case reported here, however, it is not established that the patient is sensitive to a product of her own body but merely that she is sensitive to a product of the body of some other human being, which may or may not be identical with the analogous product of her own body. It is well known that the tissues of one individual, skin for example, when grafted on the body of another person, seldom survive, while autogenous transplants are nearly always successful. It is obviously impossible to solve this problem in this particular case, since it is not possible to test this woman with an extract of her own pituitary gland.

SENSITIZATION PHENOMENA FOLLOWING THE USE OF SODIUM MORRHUATE FOR THE CHEMICAL OBLITERATION OF VARICOSE VEINS

LOUIS L. PRAIER, M.D. AND S. WILLIAM BECKER, M.D.
CHICAGO

Untoward reaction in the form of a cutaneous eruption or a nitritoid crisis was observed in seven out of 176 patients who received 783 injections of 5 per cent sodium morrhuate (Searle) in the Dermatology Clinic for the chemical obliteration of varicose veins. Two patients received further sodium morrhuate injections without recurrence of the eruption so the connection is not proved in these two instances.

The reactions were: urticarial eruption on the leg, two cases; urticarial eruption on leg and arm, one case; urticaria on arms one case; pruritus, erythema and edema of arms one case; pruritic erythematous eruption on leg, one case; weakness for two days, one case. Injections were continued in one patient with urticarial wheals at sites of previous injections and a nitritoid crisis appeared after six injections, accompanied by cutaneous reaction only. The reaction seen most frequently consisted of grouped urticarial wheals at the sites of previous injections which can be attributed with certainty to sensitization to sodium morrhuate.

EXPERIMENTAL WORK

The skin was tested with 5 per cent solution of sodium morrhuate (1) by the scratch method, (2) by intracutaneous injection of 0.03 cc (intra-dermal test), followed (3) in one week by a second intra-dermal injection of the same amount (for the Arthus phenomenon) and (4) in twenty-four hours by intravenous injection (for the Schwartzman phenomenon). Interpretation of results was difficult owing to the irritating nature of the solution. The scratch test was interpreted as negative in nine patients and positive in two patients both of whom showed signs of hypersensitivity to the drug. Intra-dermal injection was made in twenty patients with slightly increased reaction in most of the patients who were hypersensitive. The difference was not sufficient to be used as a guide. Repeated injection for the Arthus phenomenon was negative in ten cases. The Schwartzman reaction was not seen in fifteen cases, repeated attempts four and six weeks later in sensitive patients did not produce it. Passive transfer was attempted with the serum of one hypersensitive patient. Subsequent intra-dermal injection of 0.03 cc. of sodium morrhuate into the skin of the recipient at the site of the injection was followed by a reaction more marked than that following any intra-dermal test, so that it was interpreted as positive. In two other recipients of the same serum, subsequent application of sodium morrhuate by the scratch method produced no abnormal reaction.

Since the 5 per cent sodium morrhuate solution is irritating it was diluted with sterile water and it was found that 0.03 cc of a 1:640 dilution produced a visible wheal in a presumably nonsensitive patient. Further study is being made with diluted material. The solution was analyzed to determine the presence of protein and the total nitrogen content. The protein was too small in amount to be determined in a 20 cc sample. Total nitrogen was 0.037 Gm per liter. If one assumes that it is all protein nitrogen the protein content would be 0.25 Gm per liter, not enough to produce sensitization.

COMMENT

Cutaneous and nitritoid reactions followed the administration of sodium morrhuate in about 3 per cent of cases. Zimmermann reported similar reactions from the drug. He also emphasized the difficulty in interpreting cutaneous tests but suggests the performance of intracutaneous tests on a patient who has lapsed (presumably from ten to fourteen days) in order to determine the development of hypersensitivity. The irritating nature of the solution suggests the advisability of using diluted material or other material, such as cod liver oil itself. This problem is being studied in this clinic. Animal

experiments are being performed which may shed some light on the method of production of sensitization. The protein content is not sufficient in itself to produce sensitization, but the sodium morrhuate may act as a haptene and sensitize susceptible individuals. The eventual production of a nitritoid crisis in one of our patients emphasizes the desirability of changing to some other substance at the first sign of hypersensitivity. It is also advisable, as stated by Zimmermann,¹ to begin with 0.5 cc of sodium morrhuate for the first injection.

INSTRUMENTS TO FACILITATE THE INSTILLATION OF PROPHYLACTIC MEDICATION OF THE EYES OF THE NEW-BORN

P. BROOKE BLAND, M.D. AND MARIO A. CASTALLO, M.D.
PHILADELPHIA

The occasional development of ophthalmia in the new-born is probably not due to the omission of the conventional prophylactic means employed but rather to faulty instillation of the bactericide instilled.

In order for the antiseptic solution used to be effective it is essential that contact be made with all parts of the conjunctival sac. Simply, as so often occurs, to expose the membrane about the palpebral fissure is by no means sufficient. By the customary manual retraction of the eyelids, free and full exposure of the conjunctival membrane is rarely afforded.

By this method only partial exposure of the sac to the germicidal solution is as a rule attained.

Manual retraction, moreover, with the gloved fingers or the gloved fingers enveloped with gauze is more or less cumbersome and often proves inadequate in assuring that the antiseptic medication is properly instilled. By this method, furthermore, the antiseptic solution used may partially be absorbed by the gauze wrapped fingers, or owing to the struggles of the infant, the material may simply fall on the lid margins and fail to reach thereby the important areas beyond.

Fig. 1—Instrument to facilitate the instillation of medication of the eyes of the new-born.

In order to overcome the difficulties inherent in digital retraction of the eyelids of the new-born, the simple implements presented herewith have been designed.

One of us (Castallo) devised the instrument shown in figure 1. A description of this has appeared elsewhere.¹

The implement shown in figure 2 is a modification of figure 1 and was designed by the senior author. In practice it is found to provide certain advantages. The small serrations on the edges of the blades of the instrument prevent slipping and, when properly placed in or rather under the orbital plates, owing to the special springlike action, it is more or less self retaining.

The blades of both instruments are so shaped that, when placed over the closed eyelids and gently separated, the eyeball with the conjunctival sac is exposed without the slightest trauma. Hence, free instillation of the antiseptic solution is assured.

Special Article**GLANDULAR PHYSIOLOGY AND THERAPY****ANTERIOR PITUITARY AND ANTERIOR
PITUITARY-LIKE SUBSTANCES****THERAPEUTIC APPLICATIONS**

EMIL NOVAK, M.D.

BALTIMORE

NOTE—This article and the articles in the previous issues of THE JOURNAL are part of a series published under the auspices of the Council on Pharmacy and Chemistry. Other articles will appear in succeeding issues of THE JOURNAL. When completed, this series will be published in book form—Ed

Up to a few years ago, efforts at anterior pituitary therapy were limited to the use of oral or hypodermic preparations, either of the anterior lobe alone or of the whole gland, in conditions of supposed deficiency, such as adiposogenital dystrophy, pituitary obesity or amenorrhea, dwarfism or infantilism. In this respect the common practice was almost analogous to the early methods of ovarian therapy in conditions of supposed ovarian hypofunction. Just as the clear differentiation of the ovarian hormones has completely changed the complexion of ovarian therapy, so have the recent advances in anterior pituitary hormonology changed the points of view and methods in pituitary organotherapy. The tendency now is to aim at hormone therapy rather than at mere gland treatment.

The important physiologic advances to which reference has been made have been fully reviewed in previous articles of this series. The present paper, like the one on estrogenic therapy, makes no pretense of being an exhaustive review, being offered rather as a brief summary and appraisal of the present status of the subject, and including only a minimum of references to the extensive and somewhat bewildering literature.

As a basis for the discussion of the therapy of the anterior lobe, the following hormones have been enumerated¹ as having their source in this structure:

- 1 The growth hormone, commonly accepted as being the product of the eosinophilic cells
- 2 The gonadotropic hormone or hormones, generally believed to be formed by the basophilic cells
- 3 The lactogenic hormone, shown by Riddle² to be the cause of lactation, but only when the mammary gland is previously subjected to the action of the estrogenic hormones
- 4 The thyrotropic hormones on which the activity of the thyroid is dependent
- 5 The fat metabolism hormone
- 6 The blood sugar raising hormone.
- 7 The adrenotropic hormone

Of all these, only the first two would seem, in the present state of knowledge, to merit any discussion from the standpoint of organotherapy. The lactogenic hormone (prolactin) may perhaps prove of clinical value as a galactagogue, but only one brief report,³

based on a very small series of cases, has so far been made on this subject. Encouraging results are said to have been obtained.

**CLINICAL CONDITIONS INVOLVING GROWTH
HORMONE**

Growth Abnormalities—The best known of these, gigantism and acromegaly, are due to excessive production of the growth hormone, most often by adenomas of the acidophilic cells. Here the problem is not one of organotherapy but of correcting the endocrine excess by means of surgery or irradiation.

As types of deficiency of the growth hormone may be mentioned the growth deficiencies characterizing the various types of pituitary dwarfism and infantilism, especially the so-called Lorain-Levi and Brissaud types. While these are believed most often to be due to adenomas of the chromophobe cells, the obvious growth deficiency would seem to justify the use of preparations containing the growth hormone. Simmonds' disease⁴ (cachexia hypophyseopriva), a rare disorder due to destructive disease of the entire anterior lobe, and characterized by emaciation, a prematurely senile appearance, amenorrhea and other symptoms, has in a few cases been treated by anterior pituitary preparations, either orally or hypodermically, but the results have not been striking.

Preparations Available—No commercial preparation of the growth hormone has as yet been recognized by the Council on Pharmacy and Chemistry of the American Medical Association, which is not surprising in view of the present inability of manufacturers to prepare it in pure forms, and the meagerness and unconvincingness of clinical reports. In this country only three commercial preparations, so far as I know, are available, viz, the "Antutrin G" of Parke, Davis & Co, the "Phyone" of the Wilson Laboratories and Anterior Pituitary Extract Squibb. These extracts all contain other active principles of the anterior pituitary in addition to the growth promoting factor. The more purified form of the growth hormone with which Evans has achieved such striking results in animals is not yet available commercially, although the manufacturers to whom it has been entrusted have been able to furnish small amounts for a few clinical and experimental studies. Engelbach⁵ in 1930 reported satisfactory growth results in a pituitary dwarf of 9 years in whom treatment with the Evans purified growth hormone was carried out, with daily injections of the substance, for nine and a half years, 27 inches (7 cm.) in height being gained during this period. Engelbach and Schaefer⁶ have recently reported encouraging results in seven cases of dwarfism. In these the growth hormone preparation (antutrin G) was combined with thyroid, which Smith⁷ has shown to increase the effect on skeletal growth. Both Evans and Reichert⁸ emphasize the importance of having such growth hormone extracts free of gonadotropic principles, which might result in excitation of sex maturity, with epiphyseal closure and the cessation of growth.

There are a few clinical reports by Cushing⁹ and others of the use of preparations of the growth hormone in cases of pituitary growth deficiency, but, on the whole, the results have not been impressive. The chief hope for the future seems to lie in the preparation of the growth hormone in a purified form. If this is accomplished, there would be reason to expect far better results than those obtainable with the admittedly uncertain preparations now available. The recommended dosage of antuitrin G is 1 to 3 cc two or three times a week.

CLINICAL CONDITIONS INVOLVING GONADOTROPIC HORMONES

An enormous impetus to anterior pituitary organotherapy was given by the discovery in 1926, by Smith and Engle in this country and Zondek and Aschheim in Germany, of the remarkable effects produced on the gonads of experimental animals by anterior pituitary implantations (see article on physiology of anterior pituitary, in this series). Because of the impracticability of implants for clinical use, and also because of the difficulty of preparing satisfactory extracts for clinical purposes this discovery in itself would not have had much therapeutic significance had it not been for the further discovery by Zondek that the urine of pregnant women, even in the earliest phases of gestation, contains large quantities of "prolan," a substance believed by Zondek to be identical with the gonad-stimulating hormones produced by the anterior lobe. It is on the presence of this factor in early stages of pregnancy that the now universally employed pregnancy tests (Aschheim-Zondek, Friedman, Schneider, Brouha and the like) are based, the principle producing in the sex glands of the injected animal changes that in most respects are similar to those produced by the pituitary hormones from the gland itself. As to the actual identity of the latter and the urinary factors, there has arisen much discussion, although this has no bearing on the reliability of the pregnancy test.

Likewise there has been much discussion as to the unity or the duality of the pituitary gonad stimulating principle. Zondek early differentiated two principles one ("prolan A") having a follicle ripening effect and having to do with the production of estrogenic substance, while the other ("prolan B") is responsible for luteinization and the production of the corpus luteum factor, "progesterin." There are many excellent investigators, however, who look on these two different effects as merely different phases in the activity of a single principle. This question, as well as that of the identity or lack of identity of the urinary and the pituitary gonad stimulating hormones, has been discussed in a previous article and need not be elaborated on here.

The practical point is that anterior pituitary-like extracts made from the urine of pregnant women have been made available commercially and have achieved wide clinical vogue in disorders in which there is a supposed deficiency of the anterior pituitary gonadotropic hormones.

Preparations Available—The chief American preparations of this type are the following (1) "Antuitrin S" (Parke, Davis & Co) prepared from the urine of pregnant women by a modification of the Zondek-Aschheim technic. It is put up in 10 cc rubber diaphragm-capped vials, each cubic centimeter containing 100 rat units. The rat unit is described as the

minimum quantity of hormone that will cause the formation of one or more corpora lutea within 96 to 100 hours when injected subcutaneously in six doses, twice daily for three days, into female white rats 30 days of age and taken from a colony the members of which become sexually mature normally in from fifty to sixty days. "Follutein" (Squibb) is described as a "sterile glycerin solution of the anterior pituitary-like gonadotropic hormone found in pregnancy urine." It is prepared from the latter by a technic essentially that described by Zondek and Aschheim. "It is then dissolved in glycerin, physiologically assayed, herkefelded and filled into 1 cc syringe containers. Each cubic centimeter contains 1,250 rat units. Before administration the content of the syringe is added to 9 cc of sterilized water, thus making 10 cc, each cubic centimeter having a potency of 125 rat units." The rat unit is described as "the minimum amount which, given in six injections on three consecutive days, produces mature follicles, hemorrhagic follicles and corpora lutea in the ovary within 100 hours after the first injection in 30-day old female rats."

It is quite possible that if the actual pituitary hormones, as obtained from the anterior lobe itself, are made available, they may prove to be much more effectual than the anterior pituitary-like principles of pregnancy urine now supplied commercially, for there seems to be much difference of opinion among investigators as to the exact source and nature of these principles, while their effect on the human ovary is certainly not what would be expected from the pituitary hormones themselves. One or two firms are now, I understand, engaged in efforts to produce the gonadotropic hormones from the gland itself, but there has as yet been no opportunity for worth while clinical investigation with them.

Functional Menorrhagia—In this very frequent and very troublesome disorder, encountered at any age during the reproductive epoch, not infrequently during puberty or adolescence, and most often at or near the menopausal phase, clinical evidence indicates the definite value of therapy with anterior pituitary-like principle from the urine of pregnant women. This plan, suggested by Novak and Hurd¹⁰ in 1931, was based on the fact that corpora lutea and progesterin are lacking in this disorder and that there is presumably a lack of the luteinizing principle of the anterior lobe.

It was thought that the injection of a luteinizing principle obtainable from the urine of pregnant women would supply this deficiency. Since such a substance produces marked luteinization of the ovaries of mice and rats, it was even at first thought that the human follicle could be luteinized and progesterin thus be produced, with a completion of the cycle and cessation of the bleeding. Opportunities to study the ovaries of patients who had received this substance have shown that the response is not at all similar to that of experimental animals and that luteinization is not produced. And yet the abnormal bleeding, in a large proportion of cases, is controlled. What the mechanism is one can only speculate, though it is obviously in some way dependent on the reciprocal functions of the anterior lobe and the ovaries.

The chief indication for such therapy is found in the cases of functional bleeding in younger women, in whom any form of radiotherapy is undesirable. In

⁹ Cushing, Harvey. Disorders of the Pituitary Gland. J. A. M. A. 76: 1871 (June 18) 1921.

¹⁰ Novak, Emil and Hurd, G. B. Am. J. Obst. & Gynec. 22: 501 512 (Oct.) 1931.

women approaching the menopause, once the diagnosis is established, radiotherapy is the method of choice, yielding success in practically 100 per cent of cases. In younger women and children, on the other hand, the frequent and often alarming recurrences of functional bleeding must be treated either by curettage, often repeatedly or by organotherapy. Transfusion is not infrequently necessary.

No method of organotherapy yields as large a proportion of successes as follows the employment of the hypophyseal-like preparations, though there are many failures. Why the treatment is so strikingly successful in some cases and so unsatisfactory in others one cannot say, but certainly a proportion of the failures must be due to the uncertainties of the preparations used, for they are notoriously prone to deterioration, even with refrigeration. For this reason some clinics prefer to prepare their own material freshly from the urine of pregnant women, while some have utilized the serum of such women. Even the rectal infusion of the urine of pregnant women has been resorted to with apparent success.

When the commercial preparations are employed, as is commonly the case, a good plan is to withhold them until the onset of the bleeding, or, if this is not too free, until it can be determined whether it is actually to be abnormally long or profuse. Daily intramuscular injections are then begun, in doses of from 100 to 200 units, depending on the severity of the bleeding. In a few cases the hemostatic effect is remarkably prompt, bleeding being checked within a matter of hours. In others the injections may have to be given for four or five days, and the bleeding may be only markedly lessened instead of being checked entirely. In still others, as already stated, there may be little or no effect on the bleeding, so that other measures may be necessary. There is no objection to the plan of beginning the injections several days before the expected bleeding, although irregularity is so common in these cases that the patient cannot usually be sure of the date of onset.

Endocrinopathic Amenorrhea—The anterior pituitary-like preparations (antuitrin S or follutein) are apparently of little or no value in the treatment of endocrinopathic amenorrhea, although, when combined with estrogenic substances (given either together or in sequence, the gonadotropic factor being administered last) they sometimes produce uterine bleeding (see paper on therapeutic applications of estrogenic substances). This method of ovarian therapy is usually combined with the administration of thyroid extract.

Adiposogenital Dystrophy (Frohlich's syndrome).—This extremely common clinical picture with its adiposity of characteristic distribution (heavy girdle about the abdomen, hips and buttocks, large busts, shoulder pads) together with amenorrhea or scanty menstruation, undoubtedly has its chief source in a functional disturbance of the anterior lobe. Whether this may be a purely functional disorder or whether there is always present a chromophobic adenoma is a question that cannot be answered at the present time. Certainly there are many adenomas which, because of their small size and their position, cannot be demonstrated by any clinical or laboratory procedure at present. It seems certain, too, not only that in most cases of adiposogenital dystrophy, the gonadotropic hormones and the fat metabolism hormones of the anterior lobe are concerned but that the metabolic disturbance involves also, and perhaps chiefly, the immediately adjoining hypo-

thalamic regions of the brain. This is indicated by the investigations of Smith and others.

The organotherapy of this condition is very unsatisfactory. The common plan utilizes various combinations of pituitary preparations, thyroid extracts, and ovarian preparations. The oral administration of pituitary preparations is looked on by most clinicians, and practically all laboratory investigators, as having no value. Other clinicians, however, employ these preparations quite extensively. Some, again, believe that while of no value in the usually advised dosage of 5 or 10 grains (0.32 or 0.65 Gm.) a day, they are effective in extremely large doses (from 60 to 100 grains [4 to 6.5 Gm.] daily). As the preparations are expensive, and as their use must be kept up for periods of many months and even years, this method would be prohibitive to most patients.

Thyroid therapy is probably of much greater value and may be used even when the basal metabolism is normal or only slightly subnormal, as is the usual rule. Comparatively small doses, for example $1\frac{1}{2}$ or 2 grains (0.09 or 0.13 Gm.) of desiccated thyroid daily will usually suffice. When there is any noteworthy loss of weight from combined pituitary and thyroid therapy, it seems likely that it is the latter which is chiefly responsible.

As for the use of the anterior pituitary-like and the ovarian hormones in an effort to correct the amenorrhea and the genital hypoplasia, the indications and the results are not different from those pertaining to the treatment of endocrinopathic amenorrhea in general (see article on therapeutic applications of estrogenic substances).

Undescended Testicle—An interesting clinical application of laboratory investigations is seen in the recent employment of the gonad stimulating preparations from the urine of pregnant women in the treatment of undescended testes. A scientific basis for this has been furnished by the observation by Engle,¹¹ in 1932 that the injection of these substances in immature monkeys brought about a descent of the testes, although this form of therapy had been employed before this (Shapiro, 1930). Goldman and Stern¹² have reported two cases of undescended testis, in which the use of injections of antuitrin S (100 units three times a week) was followed in a short time by descent of the gonads.

In a series of six boys suffering with the same condition, Sexton¹³ obtained successful results in four. A very recent paper by Cohn¹⁴ reports that similar treatment (with antuitrin S) was successful in five of six cases. In some of these the descent of the testis seems to have occurred with amazing rapidity. For example, in a boy of 11 the undescended right gonad previously palpable at about the middle of the inguinal canal, "descended six hours after the injection of anterior pituitary-like substance and remained well down after four months." Finally, reference may be made to the very recent study by Aberle and Jenkins¹⁵ of the effects of this form of organotherapy in both human beings and monkeys. In two of four boys receiving the treatment the testes descended but in

¹⁵ Aberle, S. B. D., and Jenkins, R. H. *Undescended Testes in Man and Rhesus Monkeys*. J. A. M. A. 103: 314-318 (Aug. 4) 1934.

only one was the descent complete. In immature monkeys complete descent occurred in one animal and only partial descent in four although Engle had obtained complete descent in eight of ten monkeys.

In view of the frequent failure of surgery to correct this condition, the endocrine treatment as outlined, would seem to be indicated in cases of undescended testis before operation is resorted to, although a far larger experience with the method is necessary before one can draw conclusions as to its degree of dependability. The recent report by Geschickter, Lewis and Hartman¹⁶ that the anterior pituitary-like gonadotropic factor produced hypertrophy of the prostate in a monkey to a degree that urethral obstruction resulted, indicates the necessity for caution in the clinical use of this principle.

Other Indications—Habitual abortion, which often presents a baffling problem, has not infrequently been treated with the anterior pituitary-like factor, in the form of either antuitrin S or follutein. The cause of this condition cannot in many cases be determined, and it is believed that some at least are due to a deficiency of the corpus luteum secretion so important for implantation and for the maintenance of fixation of the ovum in the early stages of pregnancy. Since no active preparation of the corpus luteum hormone (progesterin) is available, it is not surprising that the pregnancy urine preparations have been employed as the next most rational means of treating this condition. Failures are common, though they are not usually reported. On the other hand, some successes have been reported, and the treatment seems a justifiable one to employ, but more needs to be known of the underlying cause or causes of this condition.

Primary dysmenorrhea, another *bête noire* of gynecologists, is a disorder of protean etiology. Many causes have been advanced and the methods of treatment suggested have been legion. The psychogenic factor is unquestionably the important one in many cases, the constitutional one in others, while in still others it seems probable that an endocrine imbalance may be concerned. No gynecologic disorder, therefore, makes greater demands on the knowledge, thoroughness and common sense of the gynecologist. A summary of the general plan of treatment is given elsewhere.¹⁷

The physiologic investigations of Reynolds¹⁸ and many others indicate that, just as estrogenic substance is the natural stimulant of the normal rhythmic uterine contractility, so progesterin and the anterior pituitary-like principle contained in pregnancy urine are inhibitors of this contractility. This fact, together with the fact that the immediate factor in the pain of primary dysmenorrhea seems to be a spasmodic contraction of the uterine musculature, has led to the suggestion that a part of the treatment in some cases—but only a part—should consist of the administration of antuitrin S or follutein beginning several days before the onset of the painful periods.

The dose suggested is from 100 to 200 units each day until the first or second day of the flow, after which most patients ordinarily suffer little pain with or without treatment. Because of the ever-present psychic factor which must be considered in the evaluation of results in such a subjective disorder, it is difficult to appraise the effect of this addition to the therapeutic

armamentarium. At times the results seem brilliant, in other cases only improvement without disappearance of the pain is reported by the patient, and in still others the results are disappointing. However, in the treatment of a disorder in which there is so much therapeutic floundering as in that of primary dysmenorrhea, the plan suggested is worthy of trial, especially as it is far more rational than most others which have been suggested. It should again be emphasized, however, that in all cases of this group there should be a comprehensive survey of the constitutional, pelvic, psychic and even sociologic status of the patient.

In 1933 Brosius and Schaefer¹⁹ reported a case of complete aspermia in which the intramuscular injection of antuitrin S (2 cc twice a week) was followed by spermatogenesis, so that at the end of nine weeks numerous motile spermatozoa were found in the semen, while the testes showed a definite increase in size. Needless to say, this observation, interesting as it is, needs confirmation through trial in a large number of cases. In two recent cases of sterility in my practice in which the responsible factor was the husband's aspermia, the method suggested here failed to produce spermatogenesis.

In 1931 Bengtson²⁰ reported striking results in sixteen cases of alopecia treated by anterior pituitary substance. He recommended the hypodermic use of a pituitary gland preparation as preferable to the oral route, although the combination of the two methods gave the most rapid response. While he considered that all these cases belong to the category of glandular alopecias, he suggested that possibly other common types of baldness might also respond to the treatment. In spite of the author's own conservatism in this regard, the paper was taken up rather sensationally by the daily press. There has been no confirmation of his observations, and Lord²⁰ and others have reported unsuccessful results from the method. There seems to be no reason to expect benefit from it except perhaps in cases of genuine hypopituitarism in which the alopecia is a part of the general picture. Even here the usual limitations and uncertainties of pituitary therapy would prevail.

SUMMARY

The employment of the growth hormone preparations is indicated in the various types of pituitary growth deficiency. The results are usually not striking and will probably not be improved until biochemists isolate the hormone and produce more potent preparations.

The anterior pituitary-like preparations are probably of no value when used alone in the treatment of amenorrhea, and even when combined with estrogenic substance the results are very little improved.

The anterior pituitary-like preparations made from pregnancy urine have appeared to give excellent results in many, though not by any means all, cases of functional uterine bleeding, so that, when this disorder is encountered in young women, in whom radiotherapy is undesirable, the method should certainly be tried.

The comparatively small group of cases thus far reported in which undescended testis has been successfully treated by the anterior pituitary-like preparations make this method seem promising and worthy of more

extended trial, especially as the surgical treatment of this condition is not as satisfactory as might be wished.

There is no objection to a trial of the anterior pituitary-like preparations in the occasional mysterious and baffling cases of habitual abortion, although the results are not much more clearly defined than is the etiology of the condition.

These preparations appear rational as adjuvants in the treatment of primary dysmenorrhea, although correction of constitutional and psychic factors is often much more important, and should never be overlooked.

As to other conditions, such as aspermia and baldness, the clinical data thus far available are much too meager to draw conclusions as to the results of treatment with the anterior pituitary-like preparations and there are physiologic reasons to make one question the value of this plan.

It is possible that the results of organotherapy in various forms of anterior hypopituitarism may be improved with preparations of the gonad stimulating hormones obtained from the anterior lobe itself.²¹
